2015 **THE DESIGN OF ROCK-FILL DAMS.**
By **J. D. Galloway** 1

Discussion:
By Cecil E. Pearce 25
H. B. Muckleston 27
Harold K. Fox 28
Charles H. Paul 29
A. Floris 30
Howard F. Peckworth 30
Oren Reed 31
Walter L. Huber 33
Samuel B. Morris 35
L. F. Harza 39
Paul Baumann 39
O. W. Peterson 40
George W. Howson 42
John E. Field 45
John H. Wilson 47
Frederick H. Fowler 49
I. C. Steele and Walter Dreyer 53
F. Knapp 64
Ralph J. Reed 64
F. J. Sanger 65
C. S. Jarvis 66
L. R. East 69
Francisco Gomez-Perez and Miguel Jinich 75
J. D. Galloway 83

2016 **MULTIPLE-STAGE SEWAGE SLUDGE DIGESTION.**
By **A. M. Rawn, A. Perry Banta, and Richard Pomeroy** 93

Discussion:
By Edward W. Moore 120
Willem Rudolfs and H. Heukelekian 122
Hermann Bach 125
C. E. Keefer 128
A. M. Rawn, A. Perry Banta, and Richard Pomeroy 129

2017 **EARTHQUAKE STRESSES IN AN ARCH DAM.**
By **Ivan M. Nelidov and Harold E. von Bergen** 133

Discussion:
By A. Floris 143
Cecil E. Pearce 143
F. W. Hanna 144
A. W. Fischer 147
Ray L. Allin 148
Ivan M. Nelidov and Harold E. von Bergen 148

2018 **GRAPHICAL REPRESENTATION OF THE MECHANICAL ANALYSES OF SOILS.**
By **Frank B. Campbell** 150

Discussion:
By Donald M. Burmister 156
A. J. Weinig 159
Carl H. Kadie, Jr. 159

No. PAGE

Carlton S. Proctor 161
T. T. Knappen 163
Jacob Feld 164
Howard F. Peckworth 164
Joel D. Justin 165
L. B. Olmstead 166
T. A. Middlebrooks 168
Frank E. Fahlquist and Waldo I. Kenerson 169
E. W. Lane 174
F. J. Sanger 177
F. Knapp 178
Charles H. Lee 178
Frank B. Campbell 182

2019 **ECONOMIC PIPE SIZES FOR WATER DISTRIBUTION SYSTEMS.**
By **Thomas R. Camp** 190

Discussion:
By Clinton L. Bogert and J. M. M. Greig 203
Charles M. Mower, Jr. 203
A. C. Michael 204
Ellwood H. Aldrich 205
M. H. Klegerman 207
F. Knapp 209
Thomas R. Camp 210

2020 **GRIT CHAMBER MODEL TESTS FOR DETROIT, MICHIGAN, SEWAGE TREATMENT PROJECT.**
By **George E. Hubbell** 214

Discussion:
By G. M. Ridenour 230
Thomas R. Camp 232
W. E. Howland 240
George E. Hubbell 242

2021 **STRUCTURAL BEHAVIOR OF BATTLE-DECK FLOOR SYSTEMS.**
By **Inge Lyse and Ingvald E. Madsen** 244

Discussion:
By H. N. Hill and R. L. Moore 267
Jonathan Jones 272
Inge Lyse and Ingvald E. Madsen 274

2022 **FLOOD ROUTING.**
By **Edward J. Rutter, Quintin B. Graves, and Franklin F. Snyder** 275

Discussion:
By Cecil S. Camp 295
R. D. Goodrich 295
E. L. Myers 298
Ralph W. Powell 298
William T. Collins 302
George E. Townsend 304
Waldo E. Smith 307
Edward J. Rutter, Quintin B. Graves, and Franklin F. Snyder 309

2023 **PIN-CONNECTED PLATE LINKS.**
By **Bruce G. Johnston** 314

Discussion:
By Harold D. Hussey 337
Bruce G. Johnston 339

No. Page

2024 **WATER-HAMMER PRESSURES IN COMPOUND AND BRANCHED PIPES.**
By **Robert W. Angus** 340

Discussion:
By K. J. DeJuhasz 377
Harold A. Thomas 378
F. Knapp 388
Martin A. Mason, Pierre F. Danel, and Antoine Craya 391
A. A. Kalinske 395
Robert W. Angus 397

2025 **NATURAL PERIODS OF UNIFORM CANTILEVER BEAMS.**
By **Lydik S. Jacobsen** 402

Discussion:
By K. Bert Hirashima 432
Merit P. White 433
Lydik S. Jacobsen 438

2026 **INCREASING THE TRAFFIC CAPACITY AND SAFETY OF THOROUGHFARES: A SYMPOSIUM** 440

CAUSES OF FAILURE IN HANDLING TRAFFIC.
By **Lewis W. McIntyre** 441

REMEDIES TO RELIEVE TRAFFIC CONGESTION.
By **Donald M. McNeil** 461

IMPROVEMENTS TO REDUCE TRAFFIC ACCIDENTS.
By **Arnold H. Vey** 474

ECONOMICS OF ALIGNMENT, GRADE, AND WIDTH.
By **E. L. Schmidt** 485

Discussion:
By John A. Oakey 497
L. W. Mahone 500
Fred Lavis 501
Hugh A. Kelly 502
Sidney J. Williams 504
Harold Nevin Carey 506
W. W. Crosby 507
Roger L. Morrison 508
W. R. Flack 509
Hawley S. Simpson 511
Charles M. Noble 513
Lewis W. McIntyre 517
Arnold H. Vey 517

2027 **RELATIVE FLEXURE FACTORS FOR ANALYZING CONTINUOUS STRUCTURES.**
By **Ralph W. Stewart** 521

Discussion:
By Frederick Shapiro 531
Dean F. Peterson, Jr. 531
George W. Housner 534
Homer M. Hadley 536
Adolphus Mitchell 537
John B. Wilbur 539
Leon Blog 542
A. Floris 544
D. B. Hall 545
Ralph W. Hutchinson 546
Arthur B. McGee 548
E. Neil W. Lane 551
Ralph W. Stewart 554

No. PAGE
2028 **DEOXYGENATION AND REOXYGENATION.**
By **C. J. Velz** 560
Discussion:
By Earle B. Phelps 573
C. J. Velz 575

2029 **PRELIMINARY DESIGN OF SUSPENSION BRIDGES.**
By **Shortridge Hardesty and Harold E. Wessman** 579
Discussion:
By A. W. Fischer 609
Jacob Karol 610
Glenn B. Woodruff and Norman C. Raab 614
Hardy Cross 617
A. A. Eremin 618
A. Fraser Rose and William A. Rose 619
Leon S. Moisseiff 622
O. H. Ammann 624
Leon Blog 626
Shortridge Hardesty and Harold E. Wessman 629

2030 **ENGINEERING ECONOMICS AND PUBLIC WORKS: A SYMPOSIUM** 635
ADVANTAGES OF ORDERLY PLANNING.
By **Frederic H. Fay** 636
INFLUENCE OF PUBLIC OPINION.
By **Daniel W. Mead** 652
HAZARDS OF UNECONOMICAL CONSTRUCTION.
By **Henry Earle Riggs** 668
AN APPEAL TO REASON.
By **William J. Wilgus** 690
Discussion:
By J. K. Finch 701
Elliott J. Dent 705
C. Frank Allen 706
Bradley G. Seitz 707
Alfred Allen Stuart 708
Pierce P. Furber 708
R. F. Bessey 713
Donald M. Baker 720
Philip W. Henry 726
H. K. Barrows 727
Harry A. Wiersema 727
J. D. Galloway 734
E. S. Martin 739
K. Bert Hirashima 741
Louis E. Ayres 742
John H. Meursinge 747
Samuel B. Folk 751
Daniel W. Mead 756
William J. Wilgus 757

2031 **DESIGN OF PILE FOUNDATIONS.**
By **C. P. Vetter** 758
Discussion:
By Hibbert M. Hill 779
Odd Albert 784
August E. Niederhoff 788
A. A. Eremin 790
Jacob Feld 791
John M. Coan, Jr. 792

No. PAGE

A. AGATZ.......... 795
D. P. KRYNINE.......... 803
C. P. VETTER.......... 806

2032 **STREAM POLLUTION IN THE OHIO RIVER BASIN: A SYMPOSIUM**.......... 812

FOREWORD.
By **George E. Barnes**.......... 814

SURVEYS FOR STREAM POLLUTION CONTROL.
By **Harold W. Streeter**.......... 815

LOW-FLOW REGULATION BY PYMATUNING RESERVOIR.
By **Charles E. Ryder**.......... 832

SANITATION PROBLEMS INCIDENTAL TO FLOODS.
By **W. L. Stevenson**.......... 844

PROGRESS IN POLLUTION CONTROL IN THE OHIO RIVER BASIN.
By **E. S. Tisdale**.......... 852

PLANNING FOR POLLUTION CONTROL AT PITTSBURGH, PENNSYLVANIA.
By **D. E. Davis**.......... 860

STREAM POLLUTION PROBLEMS AT CINCINNATI, OHIO.
By **J. E. Root**.......... 868

WHAT CAN BE DONE ABOUT STREAM POLLUTION?
By **Abel Wolman**.......... 874

Discussion:
By D. E. DAVIS.......... 878
L. S. MORGAN.......... 879
C. A. HOLMQUIST.......... 882
ROBERT SPURR WESTON.......... 883
KARL IMHOFF.......... 885
HENRY D. JOHNSON, JR.......... 885
CHARLES M. REPPERT.......... 887
EDWIN K. MORSE.......... 889
JAMES H. LEVAN.......... 889
JOHN C. H. LEE.......... 891
W. H. WISELY.......... 892
F. C. DUGAN.......... 894
G. M. RIDENOUR.......... 895
ARTHUR W. BAUM, JR.......... 897
G. R. SCOTT.......... 898
DON E. BLOODGOOD.......... 901
W. L. STEVENSON.......... 902
D. E. DAVIS.......... 902

2033 **PRACTICAL METHODS OF RE-ZONING URBAN AREAS.**
By **Hugh E. Young**.......... 904

Discussion:
By ROBERT D. KOHN.......... 928
MYRON D. DOWNS.......... 928
HARLAND BARTHOLOMEW.......... 930
BENJAMIN SALTZMAN.......... 933
G. H. HERROLD.......... 936
HUGH E. YOUNG.......... 938

2034 **ECONOMIC ASPECTS OF ENERGY GENERATION: A SYMPOSIUM**.......... 942

PROGRESS IN THE GENERATION OF ENERGY BY HEAT ENGINES.
By **Geo. A. Orrok**.......... 943

HYDRO-GENERATION OF ENERGY.
By **Frank H. Rogers**.......... 952

No. Page

IMPROVEMENTS IN THE UTILIZATION OF ENERGY.
By **Joel D. Justin** 971

COST OF GENERATION OF ELECTRIC ENERGY.
By **Philip Sporn** 984

SOCIAL IMPLICATIONS OF TECHNOLOGICAL TRENDS IN THE POWER INDUSTRY.
By **Ralph E. Freeman** 995

ELECTRIC POWER IN ECONOMIC PERSPECTIVE.
By **B. Alden Thresher** 1001

Discussion:

By W. S. Finlay, Jr. 1009
R. M. Riegel 1014
Ralph Bennett 1015
J. M. Mousson 1018
Ben C. Sprague 1019
V. M. Marquis 1022
R. L. Sackett 1023
D. J. McCormack 1024
I. E. Moultrop 1025
M. M. Samuels 1026
E. W. Kramer 1031
Paul E. Gisiger 1034
F. A. Dale 1036
Ray S. Quick 1037
F. Knapp 1039
D. S. Jacobus 1041
Joel D. Justin 1044
Philip Sporn 1045

2035 **COST OF ENERGY GENERATION: SECOND SYMPOSIUM ON POWER COSTS** .. 1050

ELEMENTS OF COST.
By **John C. Page** 1051

HEAT-GENERATED ENERGY.
By **C. F. Hirshfeld and R. M. Van Duzer, Jr.** 1060

HYDRO-GENERATED ENERGY.
By **H. K. Barrows** 1088

COMBINED ENERGY GENERATION.
By **Ezra B. Whitman** 1115

DEPRECIATION AND OBSOLESCENCE.
By **Maurice R. Scharff** 1127

RECAPITULATION.
By **W. F. Uhl** 1139

Discussion:

By Joel D. Justin 1149
Frank H. Mason 1152
W. V. Burnell 1153
Daniel W. Mead 1154
A. G. Christie 1160
William E. Rudolph 1164
Louis Elliott 1166
H. G. Gerdes 1167
Leverett S. Lyon 1173
John T. Madden 1177
R. L. Thomas 1181
Theodore B. Parker 1183
Philip Sporn 1186
L. N. McClellan 1188

No. Page
James C. Bonbright 1192
R. Robinson Rowe 1196

C. F. Hirschfeld and R. M. Van Duzer, Jr. 1207
H. K. Barrows 1208
Maurice R. Scharff 1209

2036 **ECONOMICS OF SEWAGE TREATMENT.**

By **George J. Schroepfer** 1210

Discussion:

By Charles Gilman Hyde 1239
Frederic Bass 1242

2037 **LABORATORY INVESTIGATION OF FLUME TRACTION AND TRANSPORTATION.**

By **Y. L. Chang** 1246

Discussion:

By Hans Kramer 1285
E. W. Lane 1286
Joe W. Johnson 1287
J. E. Christiansen 1293
W. H. Huang 1297
Lorenz G. Straub 1298
Hunter Rouse 1303
Y. L. Chang 1308

2038 **THE THREE-POINT PROBLEM IN A CO-ORDINATED FIELD.**

By **R. Robinson Rowe** 1314

Discussion:

By Oscar S. Adams 1325
George D. Whitmore 1326
John R. Jahn 1328
R. Robinson Rowe 1332

2039 **TRANSPORTATION OF SAND AND GRAVEL IN A FOUR-INCH PIPE.**

By **G. W. Howard** 1334

Discussion:

By Fred R. Brown 1349
Josef E. Montgomery 1350
Elliott J. Dent 1351
David L. Neuman 1357
Morrough P. O'Brien and R. G. Folsom 1359
R. L. Vaughn 1362
M. P. Durepaire 1369
Pierre F. Danel 1372
H. S. Gladfelter 1374
G. W. Howard 1376

2040 **PRINCIPLES APPLYING TO HIGHWAY ROAD-BEDS.**

By **Ira B. Mullis** 1381

Discussion:

By A. F. Greaves-Walker 1402
H. Z. Schofield 1403
W. H. Campen 1403
Bernard E. Gray 1405
W. J. Turnbull 1411

No. Page

Bert Myers 1412
E. Neil W. Lane 1416
Ira B. Mullis 1418

2041 **WATER-SOFTENING PLANT DESIGN.**
By **W. H. Knox** 1425

Discussion:
By Philip Burgess 1436
A. Elliott Kimberly 1437
L. R. Howson 1440
Charles P. Hoover 1441
M. H. Klegerman 1443
Rollin F. MacDowell 1445
D. E. Davis 1447
W. H. Knox 1448

2042 **AERODYNAMICS OF THE PERISPHERE AND TRYLON AT WORLD'S FAIR.**
By **Alexander Klemin, Everett B. Schaefer, and J. G. Beerer, Jr.** 1449

Discussion:
By Elliott G. Reid 1469
Karl Arnstein 1470
W. B. Klemperer 1471

2043 **RELATION OF RAINFALL AND RUN-OFF TO COST OF SEWERS.**
By **John A. Rousculp** 1473

2044 **OBSERVED EFFECTS OF GEOMETRIC DISTORTION IN HYDRAULIC MODELS.**
By **Kenneth D. Nichols** 1488

Discussion:
By Herbert W. Ehrgott 1510
E. H. Taylor 1515
Herbert D. Vogel 1517
Kenneth D. Nichols 1520

2045 **BEAM CONSTANTS FOR CONTINUOUS TRUSSES AND BEAMS.**
By **George L. Epps** 1522

Discussion:
By C. W. Deans 1530
George W Lamb 1532
A. A. Eremin 1537
Leo Legens 1537
George L Epps 1540

2046 **SOLUTION OF EQUATIONS IN STRUCTURAL ANALYSIS BY CONVERGING INCREMENTS.**
By **George H. Dell** 1543

Discussion:
By A. Floris 1555
L. E. Grinter 1556
A. A. Eremin 1558
George H. Dell 1558

2047 **MOTOR TRANSPORTATION—A FORWARD VIEW: A SYMPOSIUM** 1562

JOINT RESPONSIBILITY OF THE AUTOMOTIVE AND THE CIVIL ENGINEER.
By **C. F. Kettering** 1563

THE TREND OF MODERN HIGHWAYS.
By **Thomas H. MacDonald** 1581

TRUNK-LINE HIGHWAYS IN METROPOLITAN AREAS.
By **Leroy C. Smith** 1586

No. Page

Discussion:
By F. Lavis 1597
Edgar Dow Gilman 1602
George Hartley 1605
Robert Kingery 1606
R. L. Morrison 1607
Roy F. Bessey 1609
Bruce D. Greenshields 1612
Robert B. Brooks 1616
H. George Altvater 1619
W. W. Crosby 1620
Thomas H. MacDonald 1621
Leroy C. Smith 1623

2048 **RECONSTRUCTION OF A PIER IN BOSTON, MASSACHUSETTS, HARBOR.**
By **Charles M. Spofford** 1625

Discussion:
By William G. Atwood 1639
John N. Ferguson 1639
John Ayer 1640
Charles M. Spofford 1643

2049 **ENERGY MASS DIAGRAMS FOR POWER STUDIES.**
By **John W. Hackney** 1644

Discussion:
By Edgar E. Foster 1654
Lyle A. Whitsit 1656
John W. Hackney 1658

2050 **MECHANICAL STRUCTURAL ANALYSIS BY THE MOMENT INDICATOR.**
By **Arthur C. Ruge and Ernst O. Schmidt** 1659

Discussion:
By John B. Wilbur 1672
William J. Eney 1676
Otto Gottschalk 1681
Arthur C. Ruge and Ernst O. Schmidt 1683

2051 **LATERAL EARTH AND CONCRETE PRESSURES.**
By **Lazarus White and George Paaswell** 1685

Discussion:
By A. E. Cummings 1701
Robert G. Hennes 1704
Robert F. Legget 1706
Charles Terzaghi 1706
Jacob Feld 1708
M. G. Spangler 1710
Raymond D. Mindlin 1714
D. P. Krynine 1718
David A. Molitor 1723
Ralph W. Stewart 1724
Lazarus White and George Paaswell 1725

2052 **A THEORY OF SILT TRANSPORTATION.**
By **W. M. Griffith** 1733

Discussion:
By Joe W. Johnson 1749
G. W. Howard 1752
Harry F. Blaney 1754
E. W. Lane 1755
O. A. Faris 1756

No. PAGE

J. E. CHRISTIANSEN 1757

THE DESIGN OF ROCK-FILL DAMS

By J. D. Galloway,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Cecil E. Pearce, H. B. Muckleston, Harold K. Fox, Charles H. Paul, A. Floris, Howard F. Peckworth, Oren Reed, Walter L. Huber, Samuel B. Morris, L. F. Harza, Paul Baumann, O. W. Peterson, George W. Howson, John E. Field, John H. Wilson, Frederick H. Fowler, I. C. Steele and Walter Dreyer, F. Knapp, Ralph J. Reed, F. J. Sanger, C. S. Jarvis, L. R. East, Francisco Gomez-Perez and Miguel Jinich, and J. D. Galloway.

Synopsis

The design of rock-fill dams is discussed in this paper. The term is defined, and a short history is given of the origin and evolution of the type, together with a description of some of the important dams that have been built. The major elements of a rock-fill dam include the foundation, the nature of the rock of which the dam is constructed, the dimensions of the loose rock-fill, settlement, the impervious element on the water face, the intermediate rubble cushion, and expansion joints. The limiting conditions under which such dams should be built are considered.

During the past 75 years there has been developed, in California and other Western States, a dam of a distinctive type which is of sufficient importance to warrant description. This is the rock-fill dam, which in recent years has been built to heights such as 270 ft at Dix, in Kentucky, or 328 ft at Salt Springs, in California. Although there is a general agreement among engineers as to the principal features of this type of dam there are sharp differences of opinion regarding details of construction. It has been thought desirable to give a description of the elements of rock-fill dams in order that the present stage of this evolution may be presented and the differences among engineers discussed.

The description includes a definition of the term, "Rock-Fill Dams," an historical sketch of the evolution of the type, with details of construction, of some representative dams, the elements of the design, the material and methods used in construction, the limiting conditions under which such dams may be built, and the behavior of the dam after completion and when subjected to the water load.

Note.—This paper was published in October, 1937, *Proceedings*.

DEFINITION AND PRINCIPLES

The principles governing the design of rock-fill dams are the result of an evolution from the first ones built by the hydraulic miners in California, following the discovery of gold in 1848. The general form in plan and cross-section, as far as design is concerned, is almost entirely empirical. Various engineers have introduced different elements into the design until a fairly uniform cross-section has been evolved. Some dams have failed, thus furnishing information as to what should not be done. Many have been constructed that have given years of service and are to be considered entirely safe. It must be borne in mind, however, that although the design of rock-fill dams is mainly based upon experience certain definite theoretical principles apply to such structures which should always be considered.

Rock-fill dams do not represent the most stable and certain type, but there are a number of reasons for their use. They are generally built in relatively remote locations where the engineer uses the material at hand for his structure. In such locations the cost is usually less than for other types, such as gravity or buttressed dams. Foundation conditions are often a determining element in selecting a rock-fill dam as the best type to be built. Judgment, which determines so much in engineering, must be depended upon in the final decision as to what type to adopt.

Rock-fill dams were evolved from the log crib dam in which a series of log cribs, filled with rock and faced with timber, formed the dam. Such structures have been built in many countries where timber is, or was, abundant. Many dams of the log crib type were built throughout the United States in the period of early development, the height ranging from 5 ft to 25 ft.

Definition.—Rock-fill dams, as now built, are composed of three elements: A loose rock-fill forming the mass of the dam; an impervious face next to the water; and a rubble cushion between the two.

The characteristic that differentiates rock-fill dams from other types is that the element resisting the thrust of the water pressure is of loose rock of varying sizes, placed as a fill at an appropriate site. In almost every case, the rock is dumped loosely in position and there is no attempt at orderly arrangement of the individual rocks; nor is there any other material introduced to bind the rocks together. The mass of rock is somewhat consolidated when placed in position and further consolidation takes place by settlement under load and the action of the weather.

Resistance to the forces imposed by water is obtained from the weight of the mass of rock in the dam. There can be no arch action; nor can there be any action such as the cantilever effect of a gravity masonry dam.

As the mass of loose rock permits the free passage of water it is necessary to provide the dam with an impervious element to make it water-tight. Several different arrangements have been tried. A combination of an earth fill backed by a rock-fill has been used, but this arrangement is not properly a rock-fill dam. In a few cases a diaphragm has been placed in the center of the dam, examples being the old Lower Otay Dam in California, with its steel diaphragm encased in concrete, or the Crane Valley Dam (California) with its masonry core wall. The most usual arrangement is to place the impervious element as a facing on the water side of the dam. This facing in the earlier dams was made of timber, but in the larger and more recent structures it has been made of concrete, usually reinforced. Sheet steel has also been used. On one structure, the Morena Dam, in California, the facing was made of uncoursed rubble masonry set in concrete. Asphalt concrete has also been proposed for this purpose.

Early in the history of rock-fill dams it was recognized that on account of the unequal settlement of the rock mass, it was necessary to interpose between the facing and the rock-fill a layer of dry uncoursed rubble laid up by hand and derrick. This rubble acts as a semi-rigid element as it is subject to less settlement than the rock-fill and permits a better distribution of the water load to the rock-fill. The dry rubble is now recognized as one of the three important elements in the rock-fill dam.

HISTORICAL

As the design of rock-fill dams, as now practiced, has been the result of an evolution, it is of interest to sketch briefly the history of the principal dams in order to illustrate the empirical methods used. Table 1 gives a list of some of the important rock-fill dams.

First Bowman Dam, California.—The first dams built by miners in California were log crib dams of the type with which they were familiar in their Eastern homes. Probably the highest one was the English Dam on the Middle Yuba River, more than 100 ft high. It was built in 1856 to a height of 79 ft, enlarged and repaired in 1876, and destroyed in 1883. It preceded the Old Bowman Dam on Canyon Creek, a tributary of the South Yuba River, built by the late Hamilton Smith, Jr., M. Am. Soc. C. E. The first part of the Old Bowman Dam was constructed in 1872 as a log crib dam about 70 ft high. In

1876, the dam was raised to a height of 100 ft. The log crib portion was left in place, but the crib idea was definitely abandoned in favor of a loose rock-fill with a dry rubble wall on both faces (see Fig. 1). The timber facing was extended to the top of the dam, being held by log stringers fastened to the rubble wall.

This dam in its major part represented the modern plan of rock-fill dams. The dry rubble wall on the down-stream face, which retained the interior fill, may have been built as a measure of economy owing to the cost of blasting the rock. The published plans of this dam show the down-stream rubble wall of a thickness varying from 14 ft to 5 ft, but when the dam was removed in 1926, the rubble was found to be only 2 ft to 3 ft thick. The loose rock was small in size and earth and quarry waste was mixed with it. The timber logs of the old crib were found in good condition and the wrought-iron drift-bolts showed little rust. The dam stood for more than 50 yr, being replaced in 1926 by a higher dam.

French Lake and First Fordyce Dams, in California.—At about the same time the Bowman Dam was built, two other rock-fill dams were constructed on the South Yuba River in California. The Eureka or French Lake Dam was built by dry rubble stone with a slope of 1 : 1 on the water face and about 0.5 : 1 on the down-stream face. There may be some loose rock in the heart of the dam. The water face was covered with timber. This dam is still in service (1937) after a life of more than 60 yr.

The First Fordyce Dam, about 75 ft high, was built of dry rubble, about 60 ft thick at the base and with slopes of about 0.25 : 1. The facing was of timber. This dam was in service about 40 yr. In 1911 an earth and loose rock-fill was placed in front of the old dam, a concrete cut-off wall built in the fill, and a concrete face on a slope of 1 : 1 substituted for the timber face. In 1926, the dam was enlarged to a height of 140 ft by a loose rock-fill on the down-stream side with a slope of 1.3 : 1, the concrete water face being continued on the slope of 1 : 1.

The aforementioned three dams (Items (1), (2) and (3), Table 1) represent a change from the older log crib type to one in which the rock-fill alone resisted the forces of the water.

Walnut Grove Dam, Arizona.—This dam on the Hassayampa River, in Arizona, was built in 1888 of dry rubble with a narrow base and steep slopes. It was 110 ft high. The section was too frail, but apparently it held water for two years. It was washed out in February, 1890, in a flood in which the dam was overtopped by the water, the spillway being too small.

Escondido Dam, California.—This dam on San Elijo Creek, in California, built in 1895 as part of an irrigation system, was probably the first of the best rock-fill type. A loose rock-fill supported an ample dry rubble wall which was faced with timber. The slope on the water face was made 0.5 : 1 and on the down-stream face, 1.25 : 1 and 1 : 1. The dam is still in service (1937).

Lower Otay Dam, California.—This dam, 130 ft high, on Otay River, in California, was built at the same time as the Escondido Dam. The dam was designed with ample slope,[2] but the impervious element was a membrane of steel plates riveted together, enclosed in concrete, and connected to a cut-off wall on the bottom and sides of the canyon. The membrane was placed directly in the center of the dam. The dam was in service for about 18 yr when it was overtopped in a flood on January 27, 1916, and washed out. The spillway was insufficient to carry the flood.

---

[2] *Engineering News*, March 10, 1898.

Bear River and Meadow Lake Dams, California.—These two dams on the Mokelumne River, in California, built 1900–1903, were about the last rock-fill dams to have the down-stream face protected by a dry rubble wall. There is a saving in the quantity of loose rock by the method, but on account of higher unit costs of the paving of the down-stream slope, it makes a more expensive dam. Fig. 2, a view of the Bear River Dam, illustrates a section common to early dams, in which both faces were laid up in rubble. The section of such dams was too frail. In one flood this dam was overtopped about 18 in. and some damage was done. Later, it was reinforced with a loose rock-fill on the down-stream side.

Some preliminary plans made by the writer for the Sabrina and Hillside Dams, on Bishop Creek, California, included a rubble facing for the down-stream slope which was not used when the dams were built. The original timber facing of Sabrina Dam is shown in Fig. 3, revealing the distortion due to settlement at places where the facing was laid on loose rock-fill. In 1929, after 20 yr in service, the facing was replaced by laying timber sleepers, between rubble, on the rock-fill.

Relief Dam, California.—This dam on the Stanislaus River, California, 140 ft high, marked what is believed to be the first use of a reinforced concrete facing. In 1906, when it was planned, Charles D. Marx, Past President and Hon. M. Am. Soc. C. E., and the writer were of the opinion that a steel-plate membrane should be enclosed in the concrete. The experiment of depending upon concrete, 36 in. thick, under a 140-ft head of water, was tried and was entirely successful.

The dam has a dry rubble wall, 100 ft thick at the bottom and 13 ft at the top, the front 5 ft being very carefully laid up and 2 ft thick next this concrete set in cement mortar. In the light of subsequent experience, these dimensions of the dry rubble seem excessive.

Morena Dam, California.—The Morena Dam, built in 1909–1912, has a height of 167 ft above the stream bed, but the cut-off wall was carried 112 ft below in a narrow gorge in the granite. The dam is of ample proportions and is noteworthy as having a facing made up of rubble stone laid in concrete 6 ft thick at the stream-bed level and decreasing to about 3 ft at the top. In addition, a layer of reinforced concrete 1 ft thick was placed on the rubble masonry rising to a point 42 ft above stream bed, above which the rubble masonry is relied upon for water-tightness.

The dam was raised 5 ft in 1916–17 and 10 ft in 1922–1923. At one time it was overtopped, but it withstood the water without damage.

Recent Dams.—Table 1 gives a list of dams with main dimensions, which have been built in the past twenty-five years. Practically all these dams are of the same type as defined above, the result of the evolution of the previous

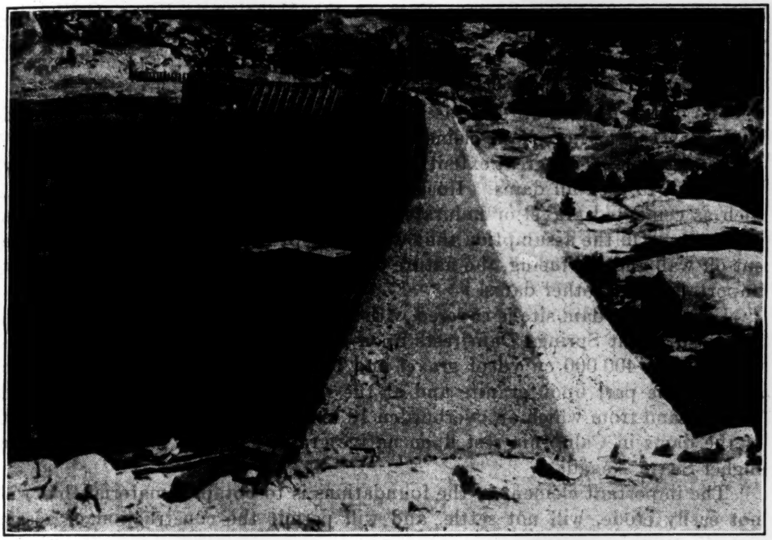

FIG. 2.—VIEW OF BEAR RIVER DAM, CALIFORNIA

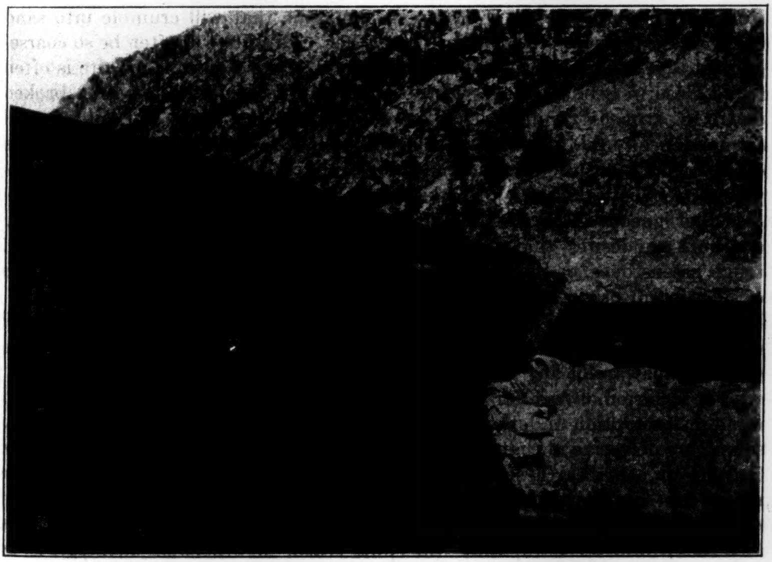

FIG. 3.—VIEW OF SABRINA DAM, BISHOP CREEK, CALIFORNIA

half century. The Salt Springs Dam on the Mokelumne River, California, 328 ft in height, represents the present maximum height of rock-fill dams.

DESIGN

The design of rock-fill dams is based upon the empirical knowledge gained in the past. The important elements are as follows.

Foundation.—To a great extent, the criteria that obtain for other dams may be applied to rock-fill dams. Rock is the best foundation but hard material, such as cemented gravel or indurated sand, will sustain the weight of such a structure. On the assumption that water is kept from the foundations by the cut-off wall and the facing, the nature of the foundation rock is not of as great importance as in other dams.

Usually, the dam site is covered with stream gravel and boulders and with hill wash. Salt Springs Dam rests upon granite, but it was necessary to remove about 400 000 cu yd of gravel and boulder over-burden. Bucks Dam rests in one part upon granite and at the north end upon a hard indurated granite sand from which an overburden 10 to 20 ft thick was removed. Most of the dams in California rest upon native granite, as they were built in the higher Sierra Nevada.

The important element in the foundations is to obtain a material that will not easily erode; will not settle, and will permit the construction of a safe cut-off wall.

Rock-Fill.—The character of the rock from which the fill is made is of the utmost importance. In granite regions the rock varies from a hard durable stone capable of standing great stresses to stone that will crumble into sand either under pressure or the action of weather. Granite will often be so coarse-grained that freezing water will disintegrate it. Hard durable granite is often found close to belts or zones where the crystalline structure has been broken down by stresses resulting from earth movements. It is not an unusual circumstance to find a hard rock cliff of excellent rock, behind which is a mass of rock wholly unsuited for the purpose. In large dams the opinion of a competent geologist familiar with rocks should be obtained from time to time.

Other igneous rocks are sometimes suitable for rock-fill dams and often they are not. Andesites that have been completely metamorphosed into hard tough greenstones, or the diorites, are good material, but the andesites may be of such recent origin as to be unsuitable.

Sedimentary rock, such as sandstone or limestone, may furnish material suitable for a rock-fill dam. The Dix Dam was made of limestone. The writer is unaware of any dam built of sandstone.

The criterion of rock for the fill is that it shall be sound and not subject to rapid disintegration under weather conditions. Many rocks, while apparently sound, are defective in that they are cut by numerous shear planes due to block faulting or other earth stresses. The rock in a dam of even moderate size must resist considerable stresses due to the weight of the rock above and, in addition, the forces arising from the weight of water. Under such conditions any rock, however hard, that will split, crush, or otherwise disintegrate, is unsuitable for a rock-fill dam.

The nature of the rock-fill is one upon which difference of opinion will develop. It is believed that the fill should be composed of individual rocks of fairly uniform size, one rock bearing directly upon another, usually expressed as "rock to rock." Any wide divergence in size will cause excessive and unequal settlements, something to be avoided wherever possible. To illustrate the idea, if one selects a sample from a mass of broken stone of fairly uniform size, it will be found extremely difficult to force the sample into the mass by added pressure. On the contrary, if a large rock, which may rest upon small gravel or sand, is given a load, it will settle into the mass by displacing the smaller grains. In the usual method of dumping rock into the fill the larger ones roll to the bottom and the smaller ones remain at the top. A graded fill results. At Salt Springs, rocks as heavy as 25 tons were used, but the usual size was about 10 tons. At Bucks (see Fig. 4), where the rock was handled entirely by trucks, the maximum size was about 3 tons.

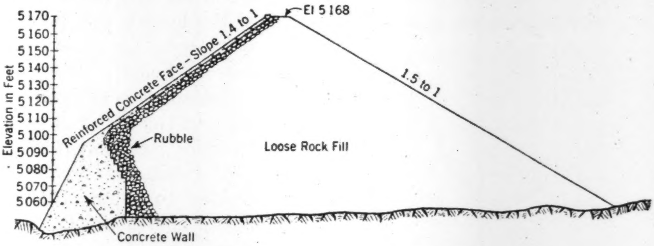

FIG. 4.—CROSS-SECTION OF BUCKS DAM

In all quarry work there is a certain amount of earth, spalls, and dust that results from the operations. Some of this waste should be rejected, but a certain quantity finds its way to the dump of the fill. It is necessary to wash this quarry waste into the fill and not allow it to accumulate in any one zone or position on the slope of the fill. At every place where the rock is dumped, there should be at least two standard fire streams of water under 100 lb pressure, constantly washing the fines into the rock. It is inevitable that the smaller rocks and most of the quarry waste will accumulate at the top of the dump. The necessary roadways require a surfacing of quarry waste. If the dam is built in vertical stages, the accumulated layer of small material at the top of any stage should be washed into the mass, but as this is rarely possible, it should be discarded. If left in place, such a layer of small material invites large local settlement, especially when the water load is applied.

It is realized that a heavier mass will result if fine material can be washed into the interstices of the fill. Such a course is advisable, only after the fill of rock has been made. The procedure should not result in a fill composed of rock in some places and masses of small material in others.

To the extent that it is possible in construction, the equipment for moving and placing the rock should be arranged to handle rock of about the same size should it be found necessary to open more than one quarry. Fills made in stages should have each stage fairly well complete before the next above is placed. Usually, in large dams, work is carried on from both sides of the canyon, in which case there should not be any great difference in the height of the stages.

Settlement.—All rock-fill dams settle. The settlement is due to the crushing of the bearing points of the rocks under increased load or to the displacement of small rocks by large ones. If the fill is made as described, the point of one rock will rest, in general, upon a surface of the rock below. As pressure increases, the rock point will be crushed, and, finally, when the water pressure is on the dam, the maximum forces will be exerted and the rock points will be crushed until a balance is established between the compressive forces and the resistance of the rock.

Weather effects will operate to increase the disintegration of the rock and this is especially true in regions with cold winters. However, in the interior mass of a dam, the effects of weather are not so great as upon the surface.

The maximum settlement of a rock-fill occurs in the first few months after being placed. Settlement of as much as 5% of the height may be expected; and it continues as the dam increases in height. After completion the settlement continues for years. In the first Bowman Dam, the vertical settlement after completion continued for 50 yr and amounted to about 1.25% of the height. This settlement was quite uniform for about 20 yr with a total of 1 ft in 100 ft of height and then it was much more gradual.

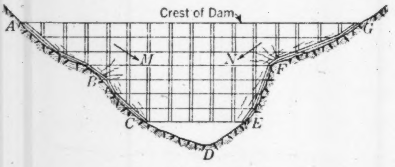

FIG. 5

Settlement in a dam is not uniform; nor is it vertical. Under usual conditions, the rock is dumped into the canyon from both sides, the fill advancing toward the center. There is a settlement of the rock toward the center as indicated by the arrows, *M* and *N*, in Fig. 5. This movement continues after the fill is complete. Fig. 5 indicates a typical profile across a canyon in which a dam may be built. The presence of a cliff, *E-F*, results in different settlements within a short distance. The configuration of the canyon wall determines to a large extent the difference in settlement.

Settlement due to the water load is an important factor in rock-fill dams. At the Dix Dam, the vertical settlement in the central portion 3 yr after completion amounted to 1.75 ft and the horizontal settlement was 1.50 ft, the height of the dam being 270 ft. This represented a movement approximately at right angles to the water-face of the dam which is mostly on a slope of 1 : 1. At the Strawberry Dam the settlement in the central section, 140 to 145 ft in height, was 1.62 ft vertical and 0.95 ft horizontal in a period of about 7 yr, indicating a movement at an angle of 75° to the slope of the water-face which is mostly 1 : 1. These measurements were taken at the top of the dam. The general indications are that the vertical settlement will continue a longer time than the horizontal, the latter being due to water pressure.

There are indications that, sometimes, movements will occur that are greater than those indicated above. This is especially true where the impervious element is placed in the center of the dam. In this location it is subjected to full water pressure. In the Crane Valley Dam, with a core wall of concrete, a horizontal movement of several feet has occurred at the top.

In the Salt Springs Dam (see Fig. 6), provision was made for ultimate settlements of 6 ft vertically and 4.2 ft horizontally.

The character and location of the settlements of this rock-fill are important as determining the design of the impervious element of the dam. The movements from the side toward the center, indicated by arrows, *M* and *N* (Fig. 5) will result in closing the expansion joints in the central section and opening those on the flanks. Dams such as Dix, Strawberry, and Salt Springs, show this effect. Again, where differential settlement is possible as at Point *F*, Fig. 5, cracks may be formed in the concrete facing. In large dams the necessity of expansion joints where the facing joins the rigid rock of the canyon wall is also indicated.

FIG. 6.—CROSS-SECTION OF SALT SPRINGS DAM IN CALIFORNIA

In the end, the depth of settlement and the question as to whether it is uniform throughout the mass of the rock-fill will be determined largely by the character of the fill, as discussed above. If layers of quarry spoil or gravel are permitted to accumulate in the rock-fill, excessive local settlements may be expected.

Cross-Section.—In the first rock-fill dams, the down-stream face was built on a slope of 1 : 1, or steeper. The up-stream slope was usually the same which resulted in a width of base of about twice the height. These steep slopes made it necessary to protect each face with rubble in order to retain the loose rock-fill.

Escondido Dam of 1895 may have been the first one to be built in which the down-stream face was composed of the unconfined loose rock. Probably Bear River and Meadow Lake Dams (Items 10 and 11, Table 1) were the last ones built with the down-stream face of rubble. In all the older dams there was a tendency to build the upper portion with steep slopes such as 0.75 : 1 and 0.5 : 1. The undoubted reason was to reduce the rock contents of the dam and the resulting cost.

There does not seem to be any good reason, except a possible saving in cost, for making the down-stream face other than the natural slope of rock dumped from cars. It is possible to have this slope as steep as 1 : 1 with large rocks only. However, in the ordinary construction of such dams, the rock varies in size and a loose rock-fill will generally assume a slope of 1.3 : 1 or

1.4 : 1 when the rocks are allowed to roll down the face of the fill. To make the slope steeper than 1.4 : 1 will usually require a second handling of the rock and there is no reason why this should be done.

The slope of the up-stream face is a subject upon which there is considerable difference of opinion. This is evidenced by the different slopes adopted by various engineers, as shown in Table 1. One of the controlling elements is found in the necessity of sufficient width of base to withstand the horizontal component of the water pressure. Experience with the Bowman Dam indicates that a base width equal to twice the height will stand without failure. Other dams noted in Table 1 have approximately the same ratios of base-to-height. However, in later dams, the ratios of width of base to the height have been increased, ranging from 2.5 : 1 up to 3 : 1. In low dams, the width of crest adds to the width of base a distance that is a factor in the total. This value decreases as the height increases. A crest width of 15 ft is a minimum, and usually a road is required across the dam. On a dam 100 ft high a 15-ft crest would add about 6% to the width of base, while on a dam 300 ft high the proportion would be about 2 per cent. The cross-sections adopted in recent dams have the ratios of base width to height, indicated in Table 2.

TABLE 2.—Ratio of Base Width to Height

No.	Dam	Height, in feet	Width of base, in feet	Ratio: Height to base
20	Dix	270	691	1 : 2.56
22	New Bowman	168	375	1 : 2.23
23	Bucks	118	340	1 : 2.90
24	Salt Springs	328	930	1 : 2.84

On an assumption of a dam 200 ft high, with a crest 15 ft wide, a down-stream slope of 1.4 : 1 and a unit weight of 100 lb per cu ft for the loose rock and with the water load, ratios of height to base of 1 : 2.25; 1 : 2.5, and 1 : 3 would have sliding factors (ratios of weight of rock to water pressure) of 4.50, 5.14, and 6 : 45, respectively. These ratios are practically constant for all heights of dams. Within the limits of the ratio of height to base width, mentioned, all such dams have ample safety against sliding. It is possible, therefore, to adopt any slope for the up-stream face that may be desired.

In Table 1 the principal face slopes are given for a number of dams. The writer believes that the slope should not be less than 0.75 : 1 and that a slope of 0.5 : 1 is too steep. Much depends upon the amount of rubble rock behind the facing. In the Relief Dam, 140 ft high, the rubble section is 100 ft thick at the bottom and 13 ft thick at the top. Such a section is stable in itself, and the slope of 0.75 : 1 on the up-stream face is ample. However, the cost of the rubble indicated that a flatter slope and less rubble would have been more economical.

In any slope steeper than the natural slope of the loose rock, it is necessary to carry up this rubble facing with the loose rock-fill in order to retain the latter Under these conditions it is necessary to maintain the derricks by which the rubble is placed, upon the face of the rubble already laid, usually a difficult operation.

In the case of the Salt Springs Dam it was decided after discussion, to make the up-stream slope of the loose rock-fill 1.3 : 1, or what was practically the natural slope (see Fig. 7). The principal reasons for this conclusion are as follows:

(1) The loose rock-fill could be built in advance of the rubble facing. To a certain extent this eliminated danger to workmen from rocks rolling down the slope. However, the controlling motive was the fact that time was given for the loose rock to settle. As settlement is a function of time and of superincumbent weight, building up the loose rock ahead of the rubble permitted the fill to take its initial settlement before the rubble was placed upon it. The settlement is usually considerably greater in the first three or four months than thereafter.

(2) The design of the rubble facing permitted the use of caterpillar derricks resting upon the rubble as it was built up. Rock for the rubble was brought in trucks and dumped down the loose rock-fill at convenient points, the caterpillar derricks moving about as required.

It is recognized that a steep slope for the up-stream face reduces the quantity of all parts of the dam—loose rock, rubble and facing—but the aforementioned advantages are believed to outweigh the increased cost of the flatter slope. This is especially true of the element of initial settlement.

It is the common custom to make the up-stream slope a curve concave to the water. This prevents buckling of the concrete facing under the settlement. Usually, the result is obtained by varying the slope. At the Strawberry Dam, several slopes, varying from 1.2 : 1 at the bottom to 1 : 1 at the top, were used. At the Salt Springs Dam, at the central section, the up-stream face was made a curve, concave to the water. Measured on a horizontal line from the theoretical slope of 1.3 : 1 (the rock at the crest elevation) the offset was 13.6 ft up stream, and at an elevation of 200 ft below, the offset was 10.5 ft down stream from the theoretical slope. In plan, the Salt Springs Dam has a crest slightly curved up stream. The face is a warped surface.

Summarizing the elements that control the design of the cross-section, the down-stream slope may be made of dumped rock, unconfined, 1.3 : 1 or 1.4 : 1; the crest width should be at least 15 ft; and the up-stream face should preferably be the natural slope, which can be made 1.3 : 1. This will result in a stable dam with base width 2.7 times the height, to which is added the crest width. To prevent buckling of the facing, the profile of the up-stream face should be made concave to the water.

Rubble Wall.—By this term is meant the layer of rock interposed between the impervious facing of the dam and the loose rock of the main fill. It is variously referred to as hand-laid or packed rock, derrick-laid rock, placed rock, etc. The term, rubble, may be open to criticism.

The function of the rubble is to act as a semi-rigid member between the rigid facing and the loose fill which is subject to settlement in several directions. The rubble also helps to bridge inequalities in the loose rock and to furnish a uniform bearing to the facing.

The rubble wall is an important part of the dam. It should be built of large rocks which are placed in positions in bearing contact with each other. The remaining spaces should be carefully filled with small rock and spalls wedged together to form a compact mass. The rock may be laid in horizontal planes, but made interlocking between layers by projecting rocks. Large rectangular rocks on the outer surface should be placed with faces roughly parallel with the slope.

If it is well built, a rubble wall is capable of resisting distortion or overturning stresses comparable to masonry walls. Note is made of well-built rubble retaining walls on the Southern Pacific Railroad where the line crosses the Sierra Nevada. A wall at the summit of the mountains, with a batter about 0.25 : 1 has carried, for many years, a double-track railroad upon which is operated the heaviest locomotives. Other instances will occur to the reader.

Table 1 gives the thickness of rubble in different dams. With the exception of Morena and Relief Dams, there is a rough correspondence in the dimensions in that the thickest part is at the bottom which narrows to a nominal thickness at the top. The idea seems to have been to vary the thickness in accordance with water pressure. In some dams the rubble was made of only nominal thickness as in the Beaver Park Dam. The thickness given for the first Bowman Dam is incorrect as the rubble facing was found to be only 2 to 3 ft thick when the dam was demolished.

At Salt Springs (Fig. 8) the writer believed that there were two controlling factors in determining the thickness. Water pressure indicated a maximum at the bottom. However, settlement of the loose rock-fill, known to be unequal, is a maximum at the crest of the dam. This factor required a considerable thickness at the crest. As built, the thickness of the rubble was made uniform from top to bottom, being 15 ft normal to the face, or about 25 ft wide on the horizontal. A similar design was followed in the Cucharas Dam where the rubble was made 30 ft thick normal to the face slope of 1 : 1.

An argument in favor of the uniform thickness of rubble of reasonable dimensions is that the derricks used to lay the rock can operate upon the wall itself without change from base to crest, which is an important item in reducing cost (see Fig. 9).

In the final analysis, the thickness of the rubble is a matter of judgment. Experience indicates that the dams built in recent years have been provided with rubble walls of sufficient thickness to perform the necessary function of distributing the water load to the loose rock-fill and of resisting excessive distortion under unequal settlement.

Cut-off Wall.—The cut-off wall is an important element in rock-fill dams, as upon it depends the connection of the facing with the bottom and sides of the canyon walls. It should be of dense concrete, wider than the facing if of concrete; and the depth into the rock of the canyon should be sufficient to cut off all visible seams in the rock and also to provide resistance to the grout injected under pressure. Grout holes should be drilled through the concrete and should penetrate deeply enough into the rock so that grout under a pressure of at least 100 lb per sq in. may be forced into any seams not closed by the wall. The design and dimensions will be determined by each locality.

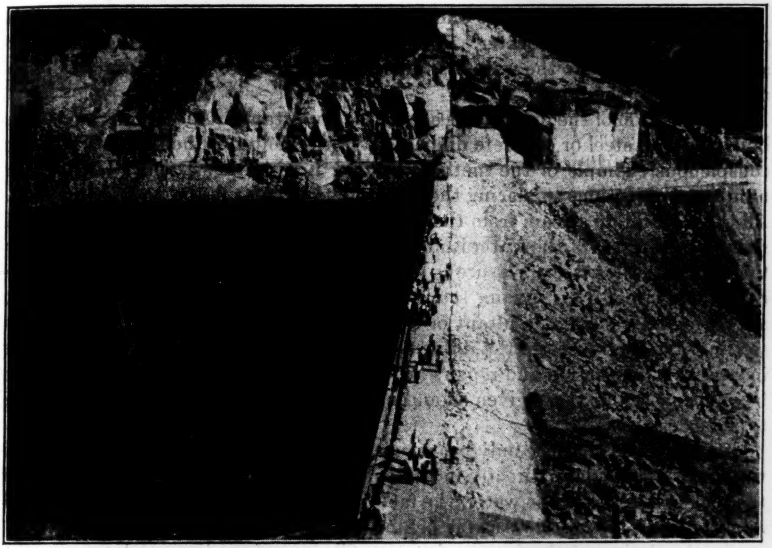

FIG. 7.—GENERAL VIEW OF SALT SPRINGS DAM, WITH SPILLWAY ON LEFT BANK

FIG. 8.—CONSTRUCTION OF RUBBLE CUSHION AND TIMBER SHEATHING AT BOTTOM OF SALT SPRINGS DAM

Facing.—Dams of the type under review must be provided with an impervious element to resist the water. As previously mentioned, the facing is the first and only resistance to the water as the loose rock and rubble offer practically no obstruction to the flow.

The position of the impervious element is important. A few dams have been built with the steel or concrete diaphragm in the center of the dam. The most conspicuous example of the method was the Lower Otay Dam. There are a number of objections to placing the impervious element in the body of the dam. All the rock-fill up stream from the diaphragm is submerged, and its function of resisting the forces of the water is nullified by partial flotation of the rock and by the fact that the water pressure is exerted where the up-stream portion of the rock cannot resist it. Again, settlement of the loose rock is not vertical but approximately along a resultant of the forces of gravity and of the water. In settling, the rock distorts the diaphragm and possibly ruptures it, and, as it is inaccessible, inspection and repairs are not possible. Other disadvantages may be mentioned, but those given should be sufficient to cause the rejection of this type of design.

It is believed that the only proper place for the impervious element is on the water-face of the dam, directly in contact with the water. In such a design all the rock acts to resist the water, the facing is open for inspection and repair, and its construction can follow as far behind the rock-fill as possible.

In the design of the facing of a rock-fill dam of medium or large size the engineer is confronted with the problem of uniting a fairly rigid facing to a mass of rock in which settlement is expected. The facing is exposed to changes of length due to temperature changes. In the spring the reservoir will be filled. In the late summer it will be partly or entirely emptied, which condition will prevail through the winter. The facing will then be exposed to ranges of temperature of 100° F, or more. In dams the facing may have a horizontal length from 500 ft to 1 000 ft, or more, and a width on the slope of from 200 ft to 500 ft. If made of concrete or steel and if it is free to move, the facing may expand and contract from 2 to 10 in. under the conditions named. However, movement cannot take place where the facing joins the walls of the canyon, which do not move.

The first factor in the problem (that of settlement which may be of the order of several feet) would indicate that the facing should be separated from the rock mass and left free to slide on the rock mass as it settles. The second factor, annual changes due to temperature would call for movements which, it is believed, cannot be permitted. Horizontal movements would take place, but in any possible plane of sliding the vertical movements, or rather movements along the inclined face of the dam, would not take place. Under low temperatures the facing (if made of steel or concrete) would contract and the movement would be downward. With rising temperatures, the movement would tend to slide the facing upward which would be resisted by the weight of the facing, friction on the sliding plane, and resistance where the facing joins the side walls of the canyon. It is believed that in any practicable case the vertical movement would not take place and that the facing, if made of steel or concrete, would buckle or crush under the forces to which it would be subjected. Timber facing, which is adapted only to relatively low dams, is sufficiently flexible to adjust itself to the changes due to settlement or to temperature changes.

It should be noted that the rubble cushion behind the facing, if properly constructed, forms a semi-rigid rock mass that resists, to a large extent, the deformation due to settlement. The differential movements between the rock-fill and the rubble wall with the facing resting upon it, is believed to take place in that zone of contact rather than on the plane between the facing and the rubble.

FIG. 9.—CONSTRUCTION OF RUBBLE CUSHION, SALT SPRINGS DAM

The plan generally followed is to fasten a steel or timber facing directly to the rock of the rubble wall. Taking account of the various factors involved and basing the opinion on experience, the writer believes that the best method is to pour a concrete facing directly upon the rubble wall, taking care that interstices are left in the rock work into which the concrete is poured in order to secure a firm bond between the two elements. In addition, grooves or chases should be built in the rubble at the joints in the concrete facing to support the slabs over the joints, thus giving a closer bond. In this manner the facing is secured to the rubble and temperature changes are resisted. In settlement, the facing follows the rubble and stresses caused by local settlement can be resisted by the reinforcement. It is possible that the facing may be crushed in places, but experience shows that this does not often occur. Reference is again made to Bucks Dam (see Figs. 3 and 10) where a concrete facing more than 1 000 ft long, poured directly on the rubble and containing no expansion joints, has not cracked in the eight years since it was constructed. At Salt Springs (see Fig. 11), the facing was poured directly on the rubble and although some minor crushing has taken place, repairs are easily made at low water. On the contrary, at the

Strawberry Dam, the design provided for a complete separation between the two elements in the upper portion of the facing, about 100 ft wide along the slope. The rubble was made smooth by a covering of cement mortar and roofing paper. The facing is in good condition but the expansion joints have opened wide at the ends of the dam and closed together at the center.

It must be recognized that these conclusions have been reached after consideration of the several contradictory factors that enter into the problem of constructing an impervious face of rigid concrete upon a rock-fill subject to continued settlement and to temperature changes.

The problem of a dam with a sheet steel facing is similar to that with a concrete face. In the two rock-fill dams listed in Table 1, with steel facing (Items 28 and 29), the steel plates were fastened by bolts to the rubble wall and were provided with expansion joints. In the highest of the two dams, the Penrose-Rosemont Dam in Colorado, the dry rubble is faced with rubble masonry laid in cement mortar 4 ft to 2 ft thick, with a plaster face next to the steel facing.

Timber Facing.—With the exception of the small Chatsworth Dam (Item 6, Table 1), the facing of the older dams was made of timber. Timber sills, 12 by 12 in., or larger, or made of hewn timbers, are buried in the rubble wall on the face of the dam. It was common practice to space them 6 ft, center to center, the sill being in vertical planes at right angles to the water-face. Such sills were fastened to the rock with large bolts. In the lower half of the facing, three layers of 2-in. or 3-in. planks, made as wide as available, were spiked to the sills, the central layer being placed at right angles to the other two. In the upper section, two layers of planks were used. Small spaces between the sheathing and the rubble were carefully filled with spalls to give as much support as possible to the facing. All joints were caulked with oakum. The result was a good water-tight facing that lasted, with minor repairs, for at least 20 yr. Some of the timbers of the first Bowman Dam lasted 50 yr. On the Sabrina Dam the timber face lasted about 20 yr, after which it was replaced by another timber face in 1929. In remote locations, where concrete is costly and timber plentiful it is good practice to use timber facing. It has the advantage of cheapness, which is often an important factor in new enterprises. Moreover, it is flexible, and its use at first permits the rock-fill to take most of its settlement before a final facing of concrete is applied.

Concrete Facing.—On the higher dams, built in recent years, the common practice has been to use reinforced concrete for facing. The small dam at Chatswork Park, in Southern California, built in 1896, was probably the first dam in which concrete was used as a facing. The Relief Dam (1907–1910) is believed to be the first of the larger dams in which reinforced concrete was used.

There was a question as to whether the concrete would be water-tight, but it was there proved that concrete would be practically water-tight under pressures up to 140-ft. Experience at Dix and Salt Springs Dams indicates that water pressures up to 300 ft can be resisted safely by concrete. There is hardly any way in which the thickness can be determined. At Dix Dam the slab is 18 in. thick under a head of about 260 ft. At Salt Springs, the thickness was made 3 ft, under a 300-ft head. The element of settlement and cracking of the concrete

FIG. 10.—CONSTRUCTION OF MONOLITHIC CONCRETE FACE, BUCKS DAM, IN CALIFORNIA

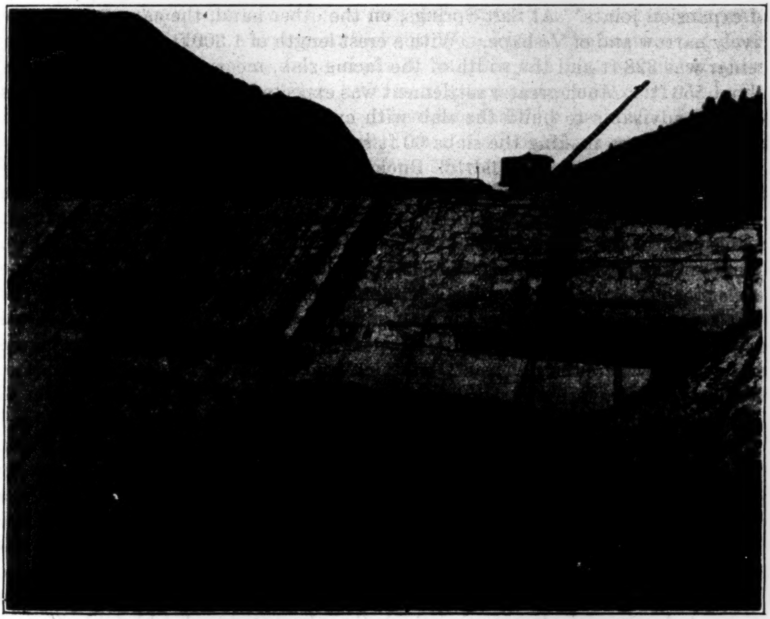

FIG. 11.—CONSTRUCTION OF CONCRETE FACING, SALT SPRINGS DAM

seems to indicate a substantial thickness of slab. It is believed that a slab thickness of 1% of the head of water will provide ample thickness. It is also believed that the slab should not be less than 12 in. thick at the top and preferably thicker where climatic conditions may lead to disintegration from frost.

At about the time the Relief Dam was under construction, a concrete facing was projected for the Morena Dam. The rubble backing was set in cement mortar which was found to be so water-tight that the concrete slab was only installed in the lower sections of the dam.

Concrete facing of rock-fill dams has usually been placed in slabs ranging from 50 to 60 ft square. Expansion joints permit adjustment under contraction and settlement of the fill. However, in the Bucks Storage Dam, the concrete facing was built without expansion joints and the reinforcement was extended across the construction joints so that the slab is practically monolithic. It may seem inconsistent to have approved two different forms of facing in two important dams being built at the same time, as was done by the writer at Bucks and at Salt Springs. However, the conditions are different. At Bucks, owing to the construction of a gravity concrete dam across the main stream as a part of the structure, the maximum width of the concrete facing measured up and down the slope is about 127 ft, while the crest length is 1 200 ft. In plan, the dam has two angles dividing it into three sections, the angles being convex to the water. Construction joints were spaced 60 ft apart horizontally and 31 ft 10 in. apart up and down the slope. The conditions were believed to warrant the omission of expansion joints. At Salt Springs, on the other hand, the canyon was relatively narrow and of V-shape. With a crest length of 1 300 ft, the height at the center was 328 ft and the width of the facing slab, measured on the slope, was about 550 ft. Much greater settlement was expected than at Bucks, and it was deemed advisable to build the slab with expansion joints, which were placed on 60-ft centers, making the slabs 60 ft square.

Reinforcement of the slab of Bucks Dam consisted of one layer of deformed bars, in the center of the slab. The vertical bars were 1 in. square spaced 12 in. center to center, and $\frac{3}{4}$ in. square bars spaced 9 in. apart, the latter being used in the upper reaches of the slab. The horizontal bars were $1\frac{1}{4}$ in. square in the lower reaches, spaced 11 in. to 12 in. apart, and 1 in. square in the upper reaches, spaced 9 in. and 11 in. apart, the bars being about 0.75% of the slab area. Reinforcement of the slab of Salt Springs Dam was made with one layer of bars in the center of the slab down to an elevation 184 ft below the spillway lip, where the slab was 27 in. thick, and two layers below that elevation. Bars are 1 in. square and 1 in. round, spaced from 8 in. to 14.5 in., center to center, depending upon position. The reinforcement was the same in both directions and did not pass either the construction joints or the expansion joints. In general, the area of bars was made about 0.5% of the area of the slab.

An exact calculation of the percentage of reinforcement is not possible although the stress can be estimated under temperature changes. The concrete of the slab is poured directly upon the rubble wall that supports it. The concrete enters into the interstices of the rock, fills the inequalities and adheres to the rock. The concrete is thus held in position, and expansion or contraction is prevented. It might be questioned whether the concrete should not be formed so as to be separated from the rock in order to permit movement when the settlement of the loose rock-fill takes place. There does not seem to be any valid reason why this should be done and there are a number of reasons why it should not. Experience has shown that concrete slabs formed on well-laid rubble do not crack from expansion and contraction of the concrete. Some settlement cracks are to be expected. However, the slab of Buck Dam (elevation more than 5 000 ft) has passed through eight winters with temperatures below zero and does not show any cracks. The leakage is negligible. The experience at other dams such as Relief or Strawberry is the same. The rubble masonry face of Morena Dam, which has been in service more than 20 yr (see Item 15, Table 1), has proved ample for the purpose.

Steel Facing.—This type of facing has been used on two dams in Colorado with success. The Skagway Dam built in 1901 is 70 ft high with the up-stream face on an angle of 30° from a vertical. The crest is 405 ft long. Steel plates 5 ft wide and 15 ft long and varying in thickness from 0.5 in. at the bottom to 0.25 in. at the top. Horizontal joints were made with butt straps and the vertical joints were made with 5 by 4-in. angles, with 5-in. legs outstanding; 2-in. by $\frac{3}{8}$-in. filler bars were riveted between the toes of the adjacent angles, temperature adjustment taking place by the flexure of the angles. The dam has been in use 35 yr (see Item 28, Table 1). The facing has performed its function, and the damage due to corrosion was found, in 1932, to be negligible.

The Penrose-Rosemont Dam, built in 1932, is 100 ft high, 580 ft long on the crest, and was built with a water-face on a slope of 0.5 : 1. The steel plates are 8.5 ft wide by 20 ft long, varying in thickness from $\frac{3}{8}$ in. at the bottom to $\frac{1}{4}$ in. at the top. Horizontal joints were made by lapping the plates, bolting them together every 18 in., and welding. Vertically, two plates were connected by a T, making a plate about 40 ft long. These lengths were connected by a contraction joint made of plate steel rolled to a semi-circular form. The plate facing was fastened to the rubble with bolts. Steel facing is entirely practicable and may have an increasing use in the future.

Construction and Expansion Joints.—The difference between the two types of joints is one of function. Construction joints representing the boundary of a concrete slab poured at one time have the concrete of the next pour directly in contact with the first. At Bucks Dam both horizontal and vertical joints were construction joints. In practically all cases, all horizontal joints become construction joints as such joints, being always in compression, never tend to open although they may be subjected to shear. Vertical joints, on the contrary, are subject to movements of the mass of the dam in which case they may either open or close. As the movements of the rock-fill under settlement are toward the center of the dam from the flanks, the joints in the central portion will tend to close and those at the abutments will open. Where there is an abrupt change in the profile of the canyon wall, as at Point *F* in Fig. 1, the joints will open. For these reasons it is advisable to build the expansion joints at the center wide open and those at the abutments closed.

In dams of some height there is a tendency for cracks to appear where the concrete facing joins the canyon walls at the cut-off wall. These cracks are due to settlement and the extent of the cracking depends upon the care used in placing the rock-fill and the rubble. At the line of contact between the concrete face and the concrete cut-off wall it is necessary to connect the two with reinforcing bars. Movement of the facing under settlement will cause bending stresses at the junction line. This movement will not all take place at one line, but there will be a zone along the contact line where the movement changes from nothing at the cut-off wall to a maximum in the body of the dam. Provision should be made in such cases for additional expansion joints which will permit motion without rupture of the concrete.

When the pressure is not great construction joints may be made in the concrete without seals, offsets being made to form keys. Such joints will generally be kept tight if the reinforcement is carried across the joint. However, it is common practice in important dams to provide some form of seal, both in construction and in expansion joints. In the latter, where movement is expected which will cause the joint to open or close, there must be a seal against the passage of water. The designs take various forms. In timber facing no such joints are necessary as there is in effect a joint at each board of the facing. In concrete, the joint usually consists of sheet copper extending into the adjoining slabs with a U-shaped section covering the open joint. The open part of the joint is usually filled with asphalt. At Salt Springs (see Fig. 12) the sheet copper was 33 in. wide, the sheets being brazed together at junctions. In steel facings, the expansion joints may be made in different ways, as illustrated in the two Colorado dams cited.

FIG. 12.—VERTICAL EXPANSION JOINTS, SALT SPRINGS DAM

Other elements of rock-fill dams, such as outlets, valves, spillways, etc., that are similar to other types of dams, do not require discussion herein. However, it should be borne in mind that a rock-fill dam may be destroyed by the passage of a flood over the crest, as in the case of the Lower Otay Dam, where a masonry dam would not have been injured. This points to the necessity of ample spillway capacity which should be free from all gates, flash-board structures, and such other construction that might cause the spillway to clog at the time of flood.

CONCLUSIONS

The paper is limited to the design of rock-fill dams. A certain amount of historical and statistical data is included because the type has been the result of evolution extending over a course of years. Rock-fill dams are not the most stable type, but there are a number of reasons for their adoption.

A rock-fill dam is defined as one made up of loose rock forming the mass of the dam, an impervious face next to the water that may be made of timber, steel, or concrete, and a mass of rubble placed between the loose rock and the face. Dams made partly of rock and partly of earth are not included.

The foundation should preferably be on solid rock, but the dam may be partly on compacted material, provided that the impervious face is connected to a cut-off wall on the bottom and sides of the canyon that will effectually shut off water.

The material composing the body of the dam should be a hard, solid rock, free from joints that would permit the rock to fracture under load, and where the crystalline structure has not been broken down by earth stresses. The material must not weather or be broken by freezing. Granite and limestone have been used, but no examples are known of the use of sandstone. The rock material must be placed in the dam in a way such that rock bears against rock. Fine material may be sluiced between the rocks of the mass after they have been placed, but not before or in such manner that rocks will rest upon the fines.

Dams have stood where the base was little more than twice the vertical height, but the section should be such that the ratio is greater. The downstream slope should be that of free falling rock, generally about 1.30 : 1 to 1.40 : 1. The slope of the water-face may range from 0.75 : 1 to 1.30 : 1, but the latter slope is believed the best for constructional and settlement purposes. The sliding factors will then be ample.

In plan, the dam should be somewhat convex to the water and the up-stream profile in section should also be a curve that is concave to the water.

The rubble cushion between the rock-fill and the impervious face should be of uniform thickness throughout its height. The thickness of the rubble is a matter of judgment and Table 1 gives the data for several dams. It is believed that a minimum thickness of 15 ft is necessary, and a greater thickness is advisable. The rubble should be carefully laid and packed with spalls.

The facing may be of timber, concrete, or steel. Timber of two and three layers of plank fastened to sleepers built in the rubble is sufficient for dams of moderate height. Concrete should be reinforced and of a thickness at least 1% of the height, or more. On low dams of considerable length, with the dam convex to the water in plan, the concrete may be laid without expansion joints, provided it is reinforced against temperature changes. In dams in narrow canyons and of considerable height, the facing should be divided into squares of approximately 50 ft on a side, by expansion joints and construction joints. Grooves or chases should be formed in the rubble and filled with concrete upon which the joint may rest. Copper seals should be used and the joints filled with asphaltum. All rock-fill dams settle over a long period of years, although the major settlement takes place in the first years. Settlement is roughly at right angles to the water-face and also along the axis of the dam from the canyon walls toward the center. It is not possible to construct a concrete face that will move independently of the settlement of the rock mass. The concrete should be poured directly on the rubble face and attached thereto by filling the openings in the rubble with concrete. On account of axial settlement, expansion joints at the central section should be built wide open and those at the ends, closed. Steel facing, made of plates and shapes, forms an excellent and durable facing which will fulfill all the functions of the other methods. Experience with steel facing has been limited to two dams, but is believed to be satisfactory.

Other details of design are not discussed because they are the same nature as those of other types. One element should be emphasized—on account of the danger of destruction if the dam is overtopped with water, the spillway should be of ample proportions and left entirely free from all obstructions, such as flash-boards, gates, etc.

The design of rock-fill dams is a matter of judgment, based upon experience. Opinions will differ, and the writer hopes that discussion will be directed to matters of design, that being the subject-matter of this paper.

DISCUSSION

CECIL E. PEARCE,[3] ASSOC. M. AM. SOC. C. E. (by letter).—There has been no good compendium on the subject of rock-fill dams and, therefore, the paper by Mr. Galloway is a timely one. The writer wishes to make several comments on it.

The sliding factors mentioned in the paragraph following Table 2 have been checked, and, at the same time, it is found that the cases which have sliding factors of 4.50, 5.14, and 6.45 have up-stream slopes of (ratios of base to height) 0.775 : 1, 1.02 : 1, and 1.54 : 1, respectively. Although it may be true that these values represent safe sliding factors in the sense usually applied to gravity dams, it may also be true that the stability of the up-stream slope is a more important criterion. If dumped rock assumes a natural slope, then does not a natural phenomenon offer a perfect index of what should be done? Carrying the case to an extreme illustrates the point. Assume that the up-stream face is vertical for a high dam (say, 300 ft high). Obviously, it would not stand; the entire vertical face would tumble, slide, and roll until equilibrium was reached at its natural angle of repose. Any slope steeper than such natural slope would mean that there were still some forces at work trying to arrive at such a slope. Any slope as flat as the angle of repose, or flatter, would mean that the material had reached a state satisfactory to the forces of Nature, and that there was no longer a condition that would cause rocks to roll down the slope.

Although it is true that Man may place these rocks somewhat carefully, and gain certain advantages in friction and interlocking, which will permit the face to stand steeper, it is also true that it is difficult to appraise the degree of success of such operations. On the other hand, one cannot assume that an up-stream face, placed as flat as the angle of repose, or flatter, has much tendency, if any, to become still flatter.

The author has stated (see heading, "Definition and Principles") that "although the design of rock-fill dams is mainly based upon experience certain definite theoretical principles apply to such structures which should always be considered." It is the writer's contention that the slope of the up-stream face is one of these points which should be based upon the rational. Considering the angles of repose which have been observed for dumped rock, the writer would recommend that the up-stream slope of important rock-fill dams be not less than 1 on 1.3, as recommended by the author in his "Conclusions."

In discussing construction and expansion joints, Mr. Galloway states that (see heading: "Design: Construction and Expansion Joints"): "In practically all cases, all horizontal joints become construction joints as such joints, being always in compression, never tend to open although they may be subjected to shear." The statement that the horizontal joints will always be in compression is quite debatable. In fact, in discussing the concrete facing, the author states (see heading, "Design: Concrete Facing"): "The concrete of the slab is poured directly upon the rubble wall that supports it. The concrete enters into the interstices of the rock, fills the inequalities, and adheres to the rock. The concrete is thus held in position, and expansion or contraction is prevented." It is agreed that the slab should be poured in this manner. Such being the case, if the job has been properly done the slab is truely supported by the fill, so that the horizontal joints will or will not be in compression, depending on whether or not the settlement shortenings overtake the original contraction of the concrete on cooling. In fact, one of the most important reasons for pouring the concrete facing as recommended is to prevent the inclined thrust down the slab and the consequent possible shearing across the corner of the joint.

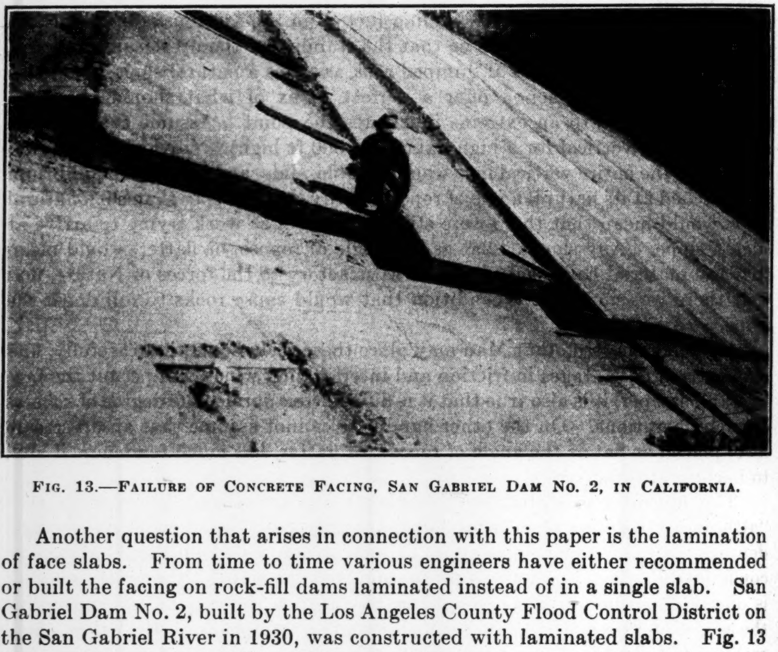

FIG. 13.—FAILURE OF CONCRETE FACING, SAN GABRIEL DAM NO. 2, IN CALIFORNIA.

Another question that arises in connection with this paper is the lamination of face slabs. From time to time various engineers have either recommended or built the facing on rock-fill dams laminated instead of in a single slab. San Gabriel Dam No. 2, built by the Los Angeles County Flood Control District on the San Gabriel River in 1930, was constructed with laminated slabs. Fig. 13 shows what happened. The settlement of the dam was irregular, and the upper slabs were offset enough at the joints so that they did not bear across the joint against the slab below. Hence, the slabs slipped over or under each other, and the corners sheared and spalled off.

If the facing had been a single slab instead of several slabs the same offset at the joints would still have left a considerable proportion of the joint area for transmitting thrust down the slope to the adjacent slab below. However, the idea of the laminated slab runs into still other undesirable conditions. It becomes difficult to anchor such a slab to the slab beneath it, even with reinforcement steel, as was done in the case shown in Fig. 13, so that there is a decided tendency for the top slab to slip on the plane top surface of the slab below. If the facing is poured as a single concrete slab on the rubble cushion, as recommended by Mr. Galloway, the slab is fixed to the rubble by bond, and by the shear in the concrete which fills the interstices in the rock so that the tendency to slide down hill is minimized. The possibility of the slab sliding down the slope has led to a general practice of establishing horizontal benches at intervals on the up-stream face of the rubble cushion, which benches are filled with concrete and act as anchors or thrust-blocks for the concrete slab.

The author's contention that the rock-fill should be sluiced while placing is a very important one, because if the fill is placed otherwise, the later rains wash the fines downward, settlement is excessive, and trouble is experienced with the concrete facing slab.

The author states that at Salt Springs the sheet-copper water-seals were brazed together. Experience with gravity dams has shown that the heat requirements of brazing seem to be such as to cause a burning of the copper, and a piling of braze upon braze, because of the rapid cooling and consequent poor job, until a kind of stiffener effect is formed.

The brazing metal, on cooling, becomes brittle, and repeated bending tests caused the braze to crack and break away from the copper. A better method has been to rivet and solder. Tinners' copper rivets, about $\frac{1}{8}$ in. in diameter, are spaced on $\frac{3}{4}$-in. centers in each of two rows, being staggered, say, $\frac{3}{4}$ in. and $1\frac{1}{2}$ in. from the end of each sheet of copper. The sheets of copper, as shipped, are tinned on the ends for about 2 in., and can be soldered easily and thoroughly. A thin film of solder results, by sweating, over the 2 in. of contact, using a soldering iron, and also a blow torch to heat the entire contact area and sweat it together. The resultant joint is as thin as possible and, consequently, stands repeated deflections without cracking.

H. B. Muckleston,[4] M. Am. Soc. C. E. (by letter).—Apparently the only recorded failures of the rock-filled type of dam were not due to defective design, but to inadequate spillway capacity. The Walnut Grove Dam, cited by the author in Table 1, Item No. 4, was designed with an up-stream slope of 20 : 47. The rear slope was 70 : 108, with a talus of loose rock on 1 : 1 slope for about one-half the height. It stood successfully for two years and would doubtless be still standing had the spillway been sufficient. The Escondido Dam (Item No. 7, Table 1) nearly as frail, is still (1937) doing its work after forty years. In both dams the slope of the water-face was much steeper than the angle of repose for loose rock, and dry rubble retaining walls were necessary to hold them. Both dams are excellent illustrations of the "great Hydraulic Principle" enunciated in 1912 by Mr. George L. Dillman[5]: "Construct one impervious surface, and build the rest of the structure to support that surface."

In solution of that principle, the author advocates reinforced concrete for the impervious surface and a backing or cushion of dry rubble masonry to minimize the effects of unequal settlement within the rock mass which is the supporting structure. Experience seems to show that this manner of construction meets the requirements successfully, but it also seems to show that it is not the only manner of construction that will do so. In every case, the designer must find the answer to the question: What type of construction will "make the owner's dollar earn the most interest?"

---

[4] Cons. Engr., Vancouver, B. C., Canada.

[5] *Transactions*, Am. Soc. C. E., Vol. LXXV (1912), p. 52.

The object of the dry rubble backing is to take up and distribute the inequalities of settlement within the rock mass so that the impervious surface will not be ruptured, either directly by water pressure, or indirectly by unequal settlement. If this end can be achieved by cheaper means than dry rubble, the end will justify its adoption. Dry rubble work is expensive and, moreover, the type of skilled labor needed for its construction seems to be nearly extinct in many localities.

The cause of settlement in a loose rock mass is mainly crushing of the individual rocks at points of contact; and inequality of settlement is mainly due to localized arching. Both can be greatly minimized if the voids in the rock mass are filled with a fairly well graded but coarse material, such as a mixture of coarse sand and quarry waste. Such a material could be sluiced into the mass from the up-stream face and allowed to take its own slope through the fill. The escaping water would find its way out through the down-stream face taking the undesirable fines with it. The resulting mass should be stable; it would be sufficiently pervious; and settlement should be relatively small and much more nearly uniform. Thus constructed, there would be no need for the rubble backing, and the thickness of the impervious surface could be fixed by consideration of impermeability alone.

For the impervious surface, many materials are available. If the dam is for head only and if storage is not a factor, a well-built timber surface should be almost everlasting. If storage is a great factor, the life of a timber face may be short but, even so, it may be the cheapest in the end.

If an adequate supply of material were available, a thick blanket of puddled clay, loaded with rock for protection, and also to confine it, would meet all requirements for impermeability. It would be sufficiently plastic to stand considerable deformation without rupture, and it should be much cheaper than concrete. If clay is not available, a blanket of well-graded sand, impregnated with a heavy asphaltic road oil, would serve as well. It probably is not possible to consolidate clay by artificial means as thoroughly as Nature has sometimes done it. The writer knows of one clay deposit (underlying the Bassano Dam, in Alberta, Canada) which was so dense that a disk 6 in. in diameter by 1 in. thick, under a head of 50 ft scarcely passed sufficient water in 24 hr to fill a tea-cup. Asphaltic concrete would be impervious—more so than cement concrete—and it would be flexible to a high degree. It would have to be loaded, however, to hold it on a slope of $1\frac{1}{2} : 1$. On one small dam, 30 ft high in a V-shaped gorge, the writer used old brick coated with, and laid up in, asphalt. It has been in service for twenty years and is apparently good for a hundred years more.

HAROLD K. FOX,[6] ESQ. (by letter).—Core walls in the center of the fill are inadvisable, as Mr. Galloway states, the principal reason being their inaccessibility.

---

[6] Dist. Engr., San Joaquin Light and Power Corp., Bakersfield, Calif.

The writer questions the advisability of using too much so-called fines in the fill because there is a hazard of obstructing drainage and also because of the possibility of the fines acting as a lubricant of the larger material and thereby facilitating slides. He has had the experience of sinking a shaft 140 ft from the top of an old rock-fill dam through the fill to bed-rock, and bases his belief on that experience.

The writer does not agree that gates cannot be used in the spillway because there are cases in which it can be done with safety, due to the character of the run-off and the possibility of maintaining an attendant to operate the gates. Gate control will often add materially to the usefulness of the project.

In regard to the stability of a rock-fill dam, the writer cannot overlook an experience with a small one about 50 ft high which was built by a logging crew. Rock was obtained from the surface at the abutments, and the facing was of lumber. Cross-sections indicated that the rock had been piled up as steeply as possible instead of allowing it to take its angle of repose. The lumber facing had been projected to form about 3 ft of flash-boards above the crest, and there is plenty of evidence of overtopping. Of course, no engineer would recommend any such conditions; however, there is value in knowing that a dam of the rock-fill type has stood under such conditions for more than forty years. It leaves little doubt as to the stability of the modern well built structures.

CHARLES H. PAUL,[7] M. AM. SOC. C. E. (by letter).—As would be expected, the author has presented, in convenient and concise form, a discussion of the more important features of design and construction of rock-fill dams, which should be of value to all engineers having direct or indirect interest in such structures. The writer is in general agreement with the author's conclusions, and with the precautionary remarks that appear throughout the text.

Under "Definition," an earth-fill backed by a rock-fill is eliminated from the rock-fill classification, which seems to be proper. The writer infers that a rock-fill faced with earth or gravel is also eliminated, and that raises this question: When a rock-fill section is stable in itself, and when an earth or gravel facing is used simply to secure water-tightness, should not such design be included under the rock-fill definition? The Minidoka Dam on Snake River, in Idaho, is an example, in which it was economical to face the rock-fill with gravel and earth, allowing this facing to wash into the voids of the rock as the placing of the facing automatically raised the water in the reservoir. That is a design that may not often be used, perhaps, but it seems to the writer that it should be classified as a rock-fill dam.

The paper states that the English Dam, built in 1856, was destroyed in 1883; it would be of interest to know how it was destroyed—whether deliberately for some reason, or by natural causes and, if so, what.

The writer would be inclined to give rock-fill dams more credit for stability than the author appears to do. Assuming good design and construction, it seems as if no question as to stability should arise, except perhaps in connection with overflow, and even in such cases it has been the writer's experience that rock-fill dams will stand considerable overflow without damage, or even danger, to the structure. It is fair to assume that the capacity and design of the spillway is an integral part of the design of a dam. Even in case of concrete dams, it is often of vital importance to have sufficient spillway capacity to prevent overflow of the main structure, not necessarily because of danger of failure, but for other reasons. Assuming a spillway with sufficient capacity, which should be provided in any case, it is the writer's opinion that where conditions are favorable, a rock-fill dam takes its place, without handicap, among the various types of approved dam designs.

---

[7] Cons. Engr., Dayton, Ohio.

The writer would not absolutely prohibit the use of spillway gates. Whether or not they should be permitted would depend largely upon the design of the gates themselves, including their control mechanism; whether or not a reliable operating crew is to be maintained at the dam at all times; whether access to the spillway gate control is such that it would not be cut off in case of emergency; and the value or importance of gate control as a feature of the project. In many cases, spillway gates are being operated and maintained with perfect safety, and are fully justified.

A. **Floris**,[8] Esq. (by letter).—In this clear, concise, and authoritative paper the statement is made that rock-fill dams resist water pressure by their own weight only. It is also true that in most rock-fill dams, the weight of water contributes to their stability. It is well known that the most important economic advantage in the design of multiple-arch dams is gained by sloping their arch barrels. The weight of water above these barrels compensates for the deficiency in the weight of multiple-arch dams against the water thrust.

With the exception of the older dams (Lower Otay[9] and East Canyon[10] constructed with a steel core-wall), and the Oued-Kébir Dam[11] with a hollow, multiple-arch core diaphragm, the dam section is made water-proof by means of wooden, masonry, concrete, or steel facing. Hence, assuming a water-tight facing and a cut-off wall at the up-stream face, the weight of water above the slope of the dam will add materially to the resistance of the structure against sliding.

Howard F. Peckworth,[12] M. Am. Soc. C. E. (by letter).—The definition of rock-fill dams, as given by Mr. Galloway, does not include those with a facing of impervious rolled-earth fill. It is perfectly evident, from a historical viewpoint, why this was done but the writer believes that a rock-fill dam with an impervious rolled-earth blanket should come under the heading of rock-fill dams especially as the rock-fill in both cases is serving the same function—that is, as weight to support the impervious section. Naturally, the grading of the rock behind the impervious section may be different, but the materials and functions of the rock-fill are the same in both cases. Mr. Galloway's paper is especially useful in defining the basic principles of design for this type of dam as developed in the West because there is no doubt that in the near future this type will be used in many variations in connection with rolled-earth fill in the South and East as well as in the West.

[12] Civ. Engr., Pacific Constructors, Inc., Shasta Dam, Redding, Calif.

At present, a graded sandstone supporting an impervious rolled-earth blanket is being used in the construction of Inland Dam, near Oneonta, Ala., for the City of Birmingham. This is one case of the use of sandstone, although not in the exact type described by Mr. Galloway; and as sandstone will undoubtedly be used some day in the type described, it is of interest to note the following characteristics of a sandstone quarry:

(1) The line of demarcation between the over-burden and the stone may be very indistinct, the over-burden grading gradually from top soil through clay, sandy clay, and decomposed or unconsolidated sandstone to good, hard, suitable sandstone. The question will arise as to exactly where suitable stone begins and many arguments can be avoided by including in the specifications, "suitable stone is that which rings under a hammer or passes a compression test of (state allowable)."

(2) In a sandstone quarry there is likely to be an excess of quarry waste; decomposed or unconsolidated sandstone, broken down by blasting to sand or fines; and included with this material may be horizontal seams of shale or vertical seams of clay or top soil. In the quarrying operations this must be expected and must be taken care of by suitable methods of wasting.

The writer checks Mr. Galloway's ratio of 1.3 to 1 for free falling sandstone rock, 3 in. to 1 in. in size, and for sandstone screenings, 0.5 in. to zero. He also checks the values, 1.3 to 1 and 1.4 to 1, for free falling sandstone rock, 15 in. to 3 in. in size.

OREN REED,[13] M. AM. SOC. C. E. (by letter).—As stated by the author, the design of rock-fill dams was developed primarily in California. Experience has established certain rules of design, which have been used in the construction of several notable structures such as the Salt Springs Dam, in California. Economy by the use of native materials is ordinarily the controlling factor in determining the selection of a rock-fill dam for any site.

Rock-fill dams are not common in Europe. However, there are a few structures of this type, one of the largest being the Porjus Dam, in Sweden, which was inspected by the writer in 1930. The dam at Porjus, 30 miles north of the Arctic Circle, consists of an earth and rock-fill, two concrete spillway sections over the natural channels, and a short concrete gravity section, giving a total length of 4 100 ft. The dam, completed in 1912, was constructed largely of earth and rock-fill because of the high cost of concrete in this remote location. Like the Crane Valley Dam, in California, the section consists of a rock-fill down stream from a center core-wall of reinforced concrete, and gravelly earth-fill, covered with rip-rap, on the up-stream side.

---

[13] Prin. Civ. Engr., Project Planning Div., TVA, Knoxville, Tenn.

The down-stream face was built on a slope of 1 on 2 and the up-stream slope varies from 1 cn 2 at the top to 1 on 3 at the toe. The crest width is 15.4 ft. The normal free-board is 5.2 ft. The material for the rock-fill was obtained from the excavation for the spillway and intake tunnel.

The two spillway sections have a total length of 648 ft, each consisting of concrete arches between concrete buttresses. The crest of the spillway sections is regulated by timber needles 15 ft long, supported by hinged steel bents, and a roller gate 16 ft in diameter and 39 ft long. The roller gate is remotely controlled from the power-house, providing close regulation of the pond level for smaller fluctuations of flow.

Due to better transportation facilities and increased knowledge of concrete construction, a multiple-arch dam was given preference when the regulation of the Sourva Lakes was under consideration. The dam at Sourva provides regulation on Lule River to increase the normal low-water flow at Porjus. This dam, completed in 1924, has a maximum height of 75 ft and a length of 785 ft.

Two more recent rock-fill dams in Sweden are situated at Sillre and Torrön. The dam at Sillre, completed in 1933, has a length of 920 ft and is constructed of rock from the power tunnel excavation. The dam is located on a marshy and morainic foundation. The down-stream face has a slope of 1 on 1.5 and the up-stream face, a slope of 1 on 1.6. The crest width is 9.85 ft, and the maximum height is about 26 ft. The water-tight part consists of stiff puddled clay, placed on the sloping up-stream face of the dam. The puddled clay has a normal thickness of 2.0 ft at the crest of the dam and 4.9 ft at the foundation. The clay blanket is joined at the bottom to a sheet-piling cut-off, which extends 13 ft to 16.5 ft in the hard, but pervious, foundation. The clay blanket has an up-stream slope of 1 on 2 and is separated from the rock-fill by a thin layer of gravel, which acts as an inverted filter. An insulating layer of peat was placed on the face of the clay blanket and heavy rubble rip-rap was constructed on the insulation material to prevent erosion by wave action. The development at Sillre is a pumped-storage project and the capacity of the reservoir is large in relation to the run-off. There is no spillway, but a sluice-way is provided which is controlled by a slide gate, 4 ft by 9 ft in section.

The dam at Torrön, completed in 1936, is a true rock-fill with a timber facing, which is fastened directly to the rock of the rubble wall. The up-stream face was built on a slope of 1 on 1, whereas the down-stream face has a slope of 1 on 1.5. The crest width is 10 ft. The timber deck was selected instead of a concrete deck because it was expected that settlement of the rock-fill might be great enough to cause dangerous cracking of a concrete deck. A low concrete cut-off wall is provided to connect the timber facing to the rock foundation.

The writer considers that a well-designed rock-fill dam is a relatively stable structure and in locations where cold temperatures are experienced, a fill dam may be preferred to a concrete structure.[14] In some cases, as noted previously, the spillway may be provided with gates with perfect safety. However, spillway regulation should be of a positive type and operated by experienced crews.

---

[14] "Preventing the Disintegration of Dams," by Oren Reed, *Civil Engineering*, January, 1933.

WALTER L. HUBER,[15] M. AM. SOC. C. E. (by letter).—At least a partial remedy for the lack of any published compilation of authentic data on rock-fill dams is found in this paper. The rock-fill dam is a type of structure which has been widely used in the western part of the United States. The author has confined his discussion to true rock-fill dams which, as he states, consist of three elements: "A loose rock-fill forming the mass of the dam; an impervious face next to the water; and a rubble cushion between the two." From this true type many variations have been developed, including important structures built in recent years wherein a very substantial section adjacent to the impervious face is of rolled fill, back of which is a loose graded rock-fill (such as San Gabriel Dam No. 1 of the Los Angeles County Flood Control District, with a maximum height exceeding 350 ft). As is indicated in the paper, the true rock-fill type is the result of an evolution from the rock-filled log crib type and from an intermediate type wherein the section was largely of uncemented, hand-laid, rubble masonry.

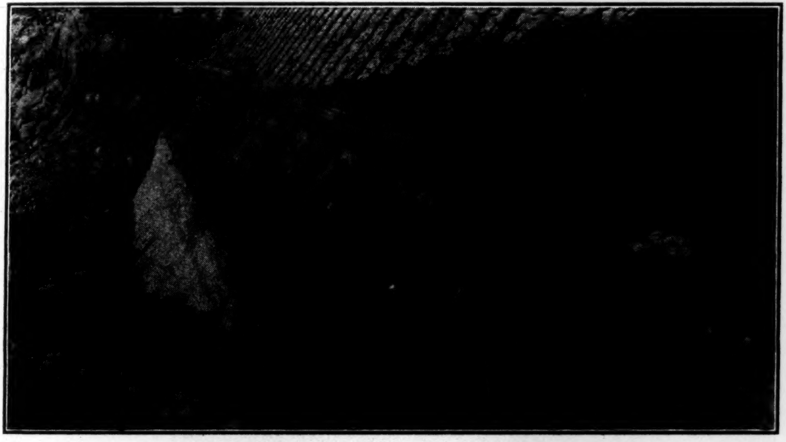

FIG. 14.—REFACING SABRINA DAM, OCTOBER, 1929

The author mentions the Bear River and Meadow Lake Dams, on the Mokelumne River, in California, built from 1900 to 1903, as about the last rock-fill dams to have the down-stream face protected by a dry rubble wall. Attention is directed to the Utica Dam, of the Utica Mining Company, on the head-waters of the North Fork of Stanislaus River, in California, which was completed to a height of 60 ft in 1908 and which has a back face of dry rubble.

Mention is made of Sabrina and Hillside Dams, on Bishop Creek, California, both of which are of the true rock-fill type, 70 and 80 ft in height, respectively. Fig. 3 is a view of the timber face of Sabrina Dam after the rock-fill had acquired most of its settlement. This is in no way indicative of the present condition of the structure. As the author has noted, the timber face was replaced after twenty years of service. Fig. 14 is offered to show the present condition of this face. The original facing was of native lodge-pole pine timber, admittedly an inferior grade of lumber, but because of the inaccessibility of the site of both Sabrina and Hillside Dams from 1908 to 1910 this was used for reasons of economy. The timber face was not laid directly on the loose fill as noted by the author, but the cushion of hand-placed rock was comparatively thin.

---

[15] Cons. Engr., San Francisco, Calif.

After twenty years of service, the original timber faces of both dams were showing signs of deterioration and leakage was increasing. Accordingly, these faces were removed and, in each case, the cushion of hand-placed rock was brought up to an even surface. Pressure-creosoted, 8-in. by 8-in. Douglas fir vertical stringers were placed in the reconstructed face of the rock cushion at intervals of 5 ft 4 in. and securely anchored by 1-in. round steel anchors which were spaced at 6-ft intervals and secured to sections of rails embedded in the dam. Directly across the stringers is a plank facing of redwood which forms the water-tight element. These planks are 3 in. by 12 in. Redwood splines, 0.5 in. by 1 in., are placed in the horizontal joints, and the end joints are splined with $\frac{1}{8}$-in. by 2-in. galvanized flat steel splines. The redwood facing varies from three layers of 3-in. planking at depths exceeding about 38 ft to a single layer for a depth of less than about 11 ft. Fig. 15 shows the face of Hillside Dam when the work of resurfacing was practically completed in September, 1930. It is believed that the life of the new faces constructed of redwood and pressure-treated Douglas fir will greatly exceed that of the original faces constructed of native timber of inferior quality. It is interesting to note that estimates indicate that reconstruction of timber faces, as required

FIG. 15.—REFACING OF HILLSIDE DAM PRACTICALLY COMPLETED, SEPTEMBER, 1930

from time to time, is more economical than the construction of a so-called permanent face under the difficulties imposed at the sites by inaccessibility and by short seasons due to high altitude.

Another advantage secured is that the flexibility of the original timber faces allowed them to follow the unequal settlement of the rock-fills and, at the same time, remain comparatively water-tight. The new faces have been applied since the settlement is substantially completed and these facings will not be subjected to the same warping. Although this type of facing has advantages for dams of lesser height, the designers of some of the very high rock-fill dams have sought a facing of more permanence and have applied it with the original construction. In each instance a degree of rigidity has resulted which has given some, although not always serious, trouble when the inevitable settlement of the rock mass occurred. In the case of San Gabriel Dam No. 2, of the Los Angeles County Flood Control District, a timber face has been installed as a temporary expedient after settlement of the rock-fill had seriously distorted the laminated concrete slab face.

A disadvantage of timber facing is the possibility of destruction by fire when the water is drawn down in the reservoir. Serious damage from this source at Sabrina Dam was traced to the carelessness of a fisherman. The owners have since enclosed all their timber-faced dams with high and substantial wire fences with locked gates.

SAMUEL B. MORRIS,[16] M. AM. SOC. C. E. (by letter).—The historical development of the rock-fill dam has been well presented in this paper and the author has outlined the general criteria for its design and construction, to the present maximum height of slightly more than 300 ft. There is one aspect relative to rock-fill dams with which the writer has long been concerned. How will the average, well-constructed, high, rock-fill dam behave during violent earthquake shocks? Earthquake accelerations up to 0.1 g are generally being applied to dams, school buildings, and other structures in regions where earthquakes of such magnitude are likely to occur.

More recent designs of concrete or masonry dams of all types in California and other parts of the United States liable to earthquakes have made provision for resistance to earthquake shock. Such designs are now made to provide for two principal types of forces acting upon a dam during such shock: (1) The forces due to acceleration acting upon the mass of the dam; and, (2) the hydrodynamic forces resulting from the motion of the dam against the still water of the reservoir bearing upon its up-stream face.

There is probably no type of structure built by Man which offers so great a potential hazard to life and property as a large dam and reservoir up stream from a heavily populated area. Proper consideration of safety is paramount. In connection with the design of a high dam so situated the writer, several years ago, took occasion to visit a large number of existing dams and to study different types from the standpoint of safety in a region where earthquakes are to be expected.

The rock-fill dam has been suggested to the writer by some engineers as being particularly suitable for use in regions liable to earthquakes, on account of its large mass and flexible character. The writer has been inclined to question the behavior of high rock-fill dams during earthquake shocks.

---

[16] Dean, School of Eng., Stanford Univ., Stanford University, Calif.

The settlement of fills during earthquakes has been general observation and common knowledge. Railway and highway fills, particularly those at bridge approaches, have settled substantially in all major earthquakes. In the Long Beach earthquake of March, 1933, a sand-spit peninsula more than 1 000 ft wide and several thousand feet long settled, and the land surface widened, causing cracks in paving aggregating as much as 5 ft. There has been serious settlement and longitudinal cracking in a large hydraulic-fill dam during an earthquake of such moderate proportions that practically no other damage to structures of any kind occurred. The reservoir was empty at the time. During the Santa Barbara earthquake of 1925, the Sheffield Reservoir was lost through complete failure of the small earth-fill dam which created it. Elsewhere, earth-fill dams have survived severe earthquakes.

During the Long Beach earthquake there was general settlement and consolidation of land surface in deep alluvial-filled valleys in the vicinity. The consolidation of alluvial materials resulted in a sudden rise of water in wells, and where ground-water was near the surface, of a large number of small jets of water flowing like little geysers, and leaving their record in fumarole-like deposits and erosions at the cracks in the ground surface through which the water flowed.

Of course, none of the physical conditions related to the foregoing observations is very closely related to the type of fill represented in properly constructed rock-fill dams. However, the settlement of mine and tunnel dumps has been observed as the result of earthquakes. Here, there may be a very marked resemblance to the normal loose rock-fill dam. The absence of placed rock, and a concrete blanket on one side of the fill, such as that used at the up-stream face of rock-fill dams, is not important in making such comparison. Of course, most of these mine or tunnel dumps will have too much fine material or will be too soft a grade of rock, and will not have included the important sluicing during rock placing. It is believed, however, that observation of such dumps may reveal some that closely resemble the loose fill of rock-fill dams. This subject is mentioned in the hope that engineers may be on the lookout for such rock-fills which may have settled during earthquakes, or which may be checked later if such earthquakes should occur in their vicinity.

With the hope that the author will comment further on the resistance of high rock-fill dams to earthquake shock the writer presents this discussion.

Mr. Galloway describes the cause and manner of settlement of rock-fill dams adequately, and yet briefly, in his first paragraph on settlement (see heading "Design: Settlement").

In discussing the cross-section (see heading, "Design: Cross-Section"; third paragraph) the author presents the accepted practice from which the typical rock-fill dam is shown to be composed of loose rock with a minimum top width of 15 ft and slopes equivalent to the angle of repose of from 1 on 1.3 to 1 on 1.4. For a thickness as great as 15 ft at the up-stream face, derrick-laid or packed rock is placed to form a semi-rigid layer to support the concrete or other impervious face.

In the case of a high dam, settlement of as much as 5% of the height may be expected owing to the spalling or crushing of point contacts between adjacent rocks in the loose rock-fill. As successive layers of rock are placed and the dam is built higher and higher these point contacts continue to spall for some time after completion of the structure until, finally, the points of contact between the rocks have sufficient area to carry the stresses involved in the dam standing without load.

These areas of contact are only sufficient to carry the normal mass of the dam itself. Many of the points of contact between the rocks will have just crushed sufficiently to carry this load at the point of incipient failure. The result is that when the water load is applied there is an immediate increase in unit stress, and the many small areas of contact already stressed to point of failure cannot carry the additional water load; renewed and further spalling takes place until the areas of these point contacts have increased sufficiently to be able to carry the forces due to the mass of the dam plus the water load on the up-stream face. This settlement may continue for months or years depending upon the rate of deterioration of the individual rocks composing the loose rock-fill.

Assume, now, that the reservoir is filled to its maximum high-water level and a severe earthquake occurs—not an earthquake involving any fault movement or permanent displacement of the rocks in the dam foundation, but merely the normal earth waves to be expected. These waves will give an oscillating motion to the foundations, exerting new and additional forces upon the rock mass. Point contact between rocks which have already spalled, first as a result of stresses due to the mass of the dam, and, second, to an additional extent, due to the water load, will immediately be stressed beyond the yield point. Additional spalling and crushing will result in immediate accumulated settlement.

This settlement may easily be much more extensive than may be computed from comparable known loading conditions. The vibrations and oscillations of the earthquake will likely tend to rotate the individual rocks in such a manner as to cause them to slide on their crushing points of contact, thus bringing about a denser compact mass of rock. Such immediate settlement and compaction during earthquakes have already been noted as a common phenomenon in all other types of fill, such as railway, highway, mine and tunnel dumps, and natural alluvial fills and sand-spits. Otherwise stable mountain slopes may yield to severe sliding, rolling, and sloughing of rock and rock masses. Such conditions were actually photographed on the slopes of San Jacinto Mountain during the San Jacinto-Hemet earthquake of 1918.

In other types of dams the vertical component of acceleration during earthquake vibrations is easily taken care of by the usual factors of safety in design. In the rock-fill dam even the vertical acceleration must be considered as it will add to the unit stresses in the point contacts, causing rock spalling and dam settlement.

The effect of sudden settlement of the rock mass upon the concrete lining on the up-stream face may easily be much more disastrous than the slow settlement that occurs during construction, during the filling of the reservoir, and thereafter. Reinforced concrete has generally been used for the highest rock-fill dams, and, therefore, reference to its use is made herein. Because of its high modulus of elasticity and lack of flexibility some failure of lining is likely to occur unless ample provision has been made in the design for such settlement.

The oscillations of the earthquake motion tend to free the rock at the face of the dam. If this rock is placed as steeply as the angle of repose there may be some likelihood of rocks being freed at the surface to roll, slide, or, possibly, to cause bulging.

The total settlement that may reasonably occur during an earthquake is difficult to foresee. Probably the settlement during construction, during reservoir filling, and for several years thereafter, will be some indication. That there will be such immediate settlement seems certain. It is quite conceivable that the settlement during earthquake shock may exceed all other settlement in magnitude. Some dams having too little free-board may settle sufficiently to cause over-topping. Fortunately, most rock-fill dams have been provided with large spillways and liberal free-board as it is well known that they cannot be over-topped with safety.

In a number of the rock-fill dams observed by the writer the irregular settlement of the up-stream face has been a substantial problem in maintaining water-tight conditions. The author suggests "that the fill should be composed of individual rocks of fairly uniform size, one rock bearing directly upon another" and that "any wide divergence in size will cause excessive and unequal settlements." Presumably, the important factor is that the size grading shall be uniform and of uniform quality of rock to avoid unequal settlement, rather than that all rock should be of the same size.

In constructing a rock-fill dam it is the general practice to sluice the fine material from the larger rock as it is placed. This fine material then tends to fill the interstices of the lower parts of the fill. As construction proceeds and the structure rises the lower part of the dam may become quite fully consolidated with fine materials in the interstices between the larger rock. The increasing load will then cause the points of contact of the larger rock carrying the load to spall off. If this process should continue sufficiently the resulting consolidation would cause an indeterminate part of the load to be carried on the fine material.

Under early normal static conditions such condition may not be entirely undesirable. However, with the passing of time, the smaller particles will become more disintegrated. Earthquake forces and vibrations may then tend to cause some greater tendency toward sliding either in whole or in part. Possibly this condition will be offset by more rapid consolidation of the small material than of the larger load-bearing rocks.

There are certain qualities inherent in high rock-fill dams which the writer believes should be considered in the design and construction of such dams. He has enumerated some of these in the hope that the author will discuss the resistance of high rock-fill dams to earthquake shock, and state the factors which in his study and experience should be provided in the design of such dams in regions where earthquakes are likely to occur.

L. F. HARZA,[17] M. AM. SOC. C. E. (by letter).—The rock-fill dam has proved its value in many places where transportation was difficult, concrete materials expensive, and other factors favorable. However, it should be pointed out that a rock-fill dam with concrete face will inevitably require some repair of the face after the initial period of settlement has passed.

This limits the proper application of this type of dam to storage reservoirs which are emptied at intervals in connection with their use, thus exposing the face for repairs. Application of the rock-fill type with concrete face is not satisfactory for dams where a large sacrifice in earnings would be entailed by emptying the reservoir, as in the case of power dams.

PAUL BAUMANN,[18] M. AM. SOC. C. E. (by letter).—In his interesting and very valuable paper the author mentions, among other dams, San Gabriel Dam No. 2 of the Los Angeles County Flood Control District. This structure was built of relatively large rock of granitic gneiss secured from a quarry approximately two miles from the dam site. The rock was hauled by means of 10-yd trucks and was placed dry, that is, without the application of sluicing water.

During the so-called New Year's storm of 1934 which swept over Southern California, heavy rainfall occurred which, in the vicinity of this dam, yielded as much as 12 in. in 24 hr. Due to the sluicing effect of this rainfall, settlement occurred in the dam, which at that time was nearly completed as far as the rock-fill proper was concerned. These settlements amounted to a maximum of about 4 per cent. Subsequent sluicing (which continued for several months) increased the maximum settlement to about 6 per cent.

During the construction of the dam a truck count was kept and recorded, from which it was possible to determine the shrinkage of the rock-fill during construction. Fig. 16 shows a curve that was plotted from the ratio of actual quantity in the dam and truck count as established at the end of each month during construction. From this diagram it is apparent that, although at the beginning of the job (that is, for the first 25-ft lift), each truck load of rock yielded 11.3 cu yd of rock-fill, it yielded only 9.4 yd at the end of the job. Hence the shrinkage due to self-compaction that occurred during construction was roughly 18 per cent. Data are from estimates and inspectors' reports.

As mentioned previously, the additional shrinkage due to natural and artificial sluicing amounted to about 6%; hence, the total shrinkage of this dam amounted to approximately 24 per cent.

During the construction of San Gabriel Dam No. 1, which consists of 6 236 000 cu yd of loose rock-fill and 3 206 000 cu yd of rolled rock-fill, the total shrinkage of the loose rock-fill amounted to about 26%, and the total shrinkage in the rolled rock-fill amounted to about 34 per cent. The loose rock-fill was placed wet; that is, with the application of approximately 2 cu yd of water to 1 cu yd of rock. The analysis shows that the application of water caused an initial shrinkage (that is, at the time of placing) of from 4 to 6 per cent. It is interesting to note that this corresponds substantially to the shrinkage in San Gabriel Dam No. 2 when water was applied after the completion of the rock-fill.

---

[17] Cons. Engr. and Pres., Harza Eng. Co., Chicago, Ill.

[18] Senior Asst. Chf. Engr., Los Angeles County Flood Control Dist., Los Angeles, Calif.

From the shrinkage measurements due to self-compaction, it follows that since the density of the rock-fill is directly proportional to the shrinkage, the average weight probably increases from 100 lb per cu ft of fill at the time of placing to approximately 125 lb per cu ft of fill at the time of completion for dams of such magnitude. This, in turn, means that the porosity of rock-fill dams of such height, particularly near the base, is relatively small due to the break-down of the contact points of the rock.

O. W. Peterson,[19] M. Am. Soc. C. E. (by letter).—A comprehensive presentation of the design of modern rock-fill dams is presented in this paper. Nevertheless, it contains several statements with which the writer is not in full accord. Mr. Galloway believes that a fill composed of individual rocks of fairly uniform size is best and that "any wide divergence in size will cause excessive and unequal settlements, something to be avoided wherever possible" (see heading, "Design: Rock-Fill"). Quarry rock ranges from fines to the maximum size, the latter depending on the physical characteristics of the rock mass and the method of quarrying. As Mr. Galloway states, the maximum size placed in Salt Springs Dam was about 25 tons, that being the size to which the larger rock fragments were reduced by secondary drilling and blasting so that they could be handled by the equipment provided. Fully 50% of the rock volume consisted of pieces heavier than 10 tons, which were loaded over the top of the power shovel buckets;

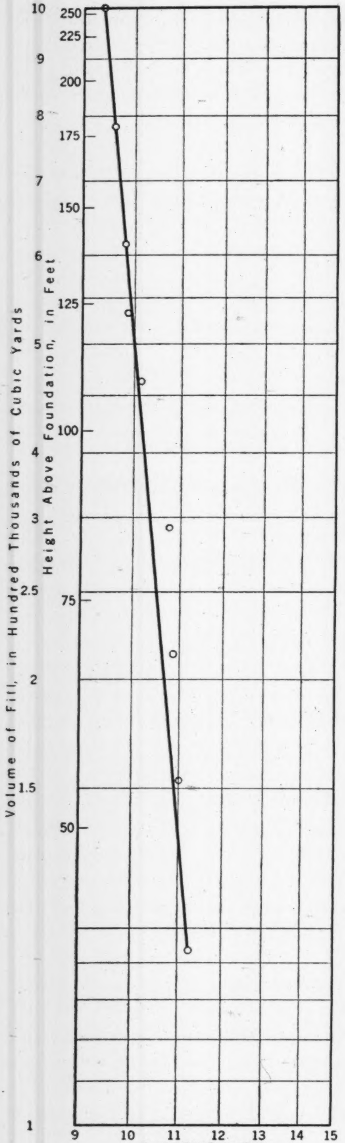

Fig. 16.—San Gabriel Dam No. 2, Shrinkage of Rock-Fill After Placing in Dam

but there was no usual size, as Mr. Galloway states. In the writer's opinion an unsegregated quarry-run mass, with excess fines wasted, will give the highest degree of contact, rock to rock, and the greatest resulting fill density. Such a fill will have ample rock-to-rock contact and will still have sufficient voids to provide adequate drainage.

---

[19] Engr. of Gen. Constr., Pacific Gas & Elec. Co., San Francisco, Calif.

Instead of stressing the importance of the nozzle pressure of the streams of water used for washing the finer rock particles into the voids between the larger rock, the writer believes the volume of water supplied should be emphasized as being of critical importance in reducing the frictional resistance to the movement of individual rocks against each other and in causing the fines to lodge in void spaces. The lubricating effect of water is invaluable in obtaining maximum settlement of a rock-fill mass during the construction period. This effect has been utilized in flattening the slopes of high tunnel dumps of hard rock free from earth, thereby stabilizing the mass. At Salt Springs Dam, as many as six 2-in. to 3-in. streams, each delivering about 600 gal per min, were used. Another advantage of the low-pressure stream is that it can be applied more economically than that of a higher pressure stream, which requires more man-power as well as more power for pumping.

At Salt Springs Dam the fines that accumulated at the top of each lift were loosened by light blasting and then washed into the voids of the underlying larger rock. This blasting was done with small charges of powder without damage to the adjacent larger rock; such vibration as occurred to the fill mass was considered beneficial in assisting settlement.

Moderately high lifts are both economical and beneficial in producing a compact fill. For a fill of 200 to 300 ft, or more, lifts of 60 to 90 ft, or more, in height can be placed successfully without undue segregation of rock. The impact of well-lubricated rock masses sliding from such heights helps to break weak or fractured rock, to remove points and thin edges, and to ram the rock firmly into stable position.

Mr. Galloway states that each stage or lift should be fairly well complete before the next above is placed. The writer can see no reason for delaying a subsequent lift after the previous one has been carried sufficiently forward to assure safety to men and equipment operating at lower levels. If the slopes are kept at a moderate angle through the use of ample sluicing water, this condition will also provide an ample margin of stability for the rock masses. Under this plan the up-stream and down-stream faces of each new lift should approximate the required final positions of the loose fill. The face that is advancing across the stream from either abutment should, in the interest of safety to the workmen, be kept back from the forward edge or crest of the underlying lift a distance about equal to twice the height of the upper fill or lift. To minimize unequal settlement, lifts advanced from the two sides of the canyon should be kept reasonably uniform in height and at the same general level.

The writer sees no reason why gates, if of conservative design and of generous proportions, should not be installed on the spillway lip of a rock-fill dam. This conclusion presupposes the necessary vigilance and intelligent operation of the gates.

George W. Howson,[20] Assoc. M. Am. Soc. C. E. (by letter).—A very thorough and complete paper on the rock-fill dam has been presented by the author. The writer was connected with the construction and operation of three of the dams listed in Table 1 and offers the following comments as the result of this experience. Three sub-headings are discussed: the "Rock-Fill," "Settlement," and the "Facing."

Rock-Fill.—At Relief and Strawberry Dams the rock-fill was spoken of as the "drop fill section," the specifications calling for the rock to be dropped into place from a height of not less than 10 ft. The idea was to hammer the rock into place. At Strawberry Dam most of the rock was transported by cableway and automatically dumped. The dropping was distributed over the entire area of the fill. It was found that drops in excess of 50 ft damaged the rock. There was a limited amount of sluicing, but several hundred cubic feet of water per second passed through the fill during a flood at the time of construction.

At Dix Dam each 16-yd car was classified as to the quality of the rock, the larger and better rock going to the up-stream half of the dam. All dirt and decomposed rock was discarded.

During the construction of a rock-fill dam all three phases of the work are generally done at the same time. As the loose fill is being placed, the rubble section is laid on the up-stream slope, and below this the concrete ribs and apron are being poured. The rubble section is built simultaneously with the loose fill and follows directly below. Progress and workmanship are best with rocks of suitable size and with one or more good faces. The selected rocks are easily delivered to the masons on the rubble wall by dumping down the up-stream slope. The rubble wall should always be extended back far enough to have a good bearing against the rock-fill section. The fill should be built to the proper lines and not carried out to meet the back of the rubble wall already built. The rubble must be supported everywhere by the compacted rock-fill.

Settlement.—All settlement is the result of crushing of the rock-to-rock bearing points, as described by Mr. Galloway. The larger the rock the fewer will be the bearing points for any given depth of fill resulting in less settlement, but construction equipment and methods generally limit the size of rock.

A fill of good granite or limestone, made as described by Mr. Galloway and properly sluiced, should not exceed 1% or 2% at the most. A reasonable settlement is to be expected and can be designed for, provided it is uniform. A settlement of 2% of the height would be reasonable. However, a rock-fill dam having a semi-rigid facing may be a partial failure with moderate settlements if the settlement of adjacent areas is not fairly regular. It is difficult to design a concrete facing to accommodate itself to large, sharp, irregular movements.

Large rocks are generally least damaged in quarrying, and have the soundest surfaces and points upon which the rock-to-rock load, as described by Mr. Galloway, is carried; consequently they offer the greatest resistance to crushing, thereby reducing settlement. Very good results may be expected if the bearing rocks weigh 2 tons and more. Smaller rock subsequently sluiced into the interstices of the bearing rocks adds weight to the fill and supporting power as the bearing points of the large rock crush.

---

[20] Berkeley, Calif.

The beneficial effect of sluicing cannot be over-stressed. Even in a fill of clean, large rock, sluicing wets all bearing surfaces, which gives a certain degree of lubrication, and assists the slipping and readjustment of the rocks to a better and more permanent position. Settlement is aided.

In considering the settlement of a rock-fill dam one generally means that settlement which occurs after the dam is completed. However, a considerable settlement is taking place in the lower parts of a dam during the construction period as the latter assumes the increased weight of the fill above. These movements are of interest to the engineer.

The rubble section settles as it follows the movement of the supporting loose fill. In most large dams with a concrete face there are vertical supporting ribs under each vertical expansion joint. The ribs are poured in advance of the concrete face. If the ribs are poured too close to the top of the rubble wall as it is being built up, the initial settlement may be sufficient to crush the green concrete ribs. At Dix Dam, it was found advisable to keep the concrete ribs about 50 ft below the top of the rubble wall.

The settlement, to a reasonable depth, is not so much a criterion of the quality of the fill as is the relative settlement of adjacent areas. In a dam in which the total settlement may be only 2%, trouble may be expected if such settlement is uneven; and uneven settlement may be expected in a fill with poor distribution of material, insufficient sluicing, or where a considerable time element exists between placing adjacent areas.

During the construction period at Dix Dam three temporary points were established on the 690-ft level (where the fill was 185 ft high) and maintained 41 days when they were covered by rock for the next lift above. During this period a flood piled up about 60 ft in front of the partly completed dam. Much water flowed freely through the rubble wall and loose fill, emerging at the base of the down-stream slope. It was impossible to measure the quantity of water passing through the dam, but the fill received a perfect sluicing below the hydraulic gradient. Fig. 17 shows a record of the settlement of these three points and is of especial interest as it shows the extent of the early settlement, the settlement caused by the flood, and the increase in settlement toward the down-stream slope of the dam. The increase in settlement toward the down-stream slope is believed to be due entirely to the fact that the poorer material was placed in the down-stream half of the dam. This section of the dam may have had some small rock separating the rock-to-rock bearing points of the larger rocks, and the small rocks were displaced by the flood. Settlement varied from 0.32% at the up-stream slope to 1.02% of the height of the fill at the down-stream slope. All these points were on the loose fill section of the dam.

Another temporary point set on the face of the rubble wall showed the following movement during the 70-day period of record before it was covered by the concrete facing. There was a movement toward the center of the canyon of 0.28 ft, an up-stream movement of 0.07 ft, and a vertical settlement of 0.28 ft. The dam at this point was 100 ft high and on the side of the canyon. Consideration should be given these movements when establishing lines for the work.

At Strawberry Dam a similar flood occurred during construction. It is believed these floods were of material benefit to both dams.

Mr. Galloway gives settlement data for Dix Dam during the first three years after its completion. Later measurements, made eleven years after completion, show the maximum settlement at the crest to be: Vertical, 2.48 ft; horizontal,

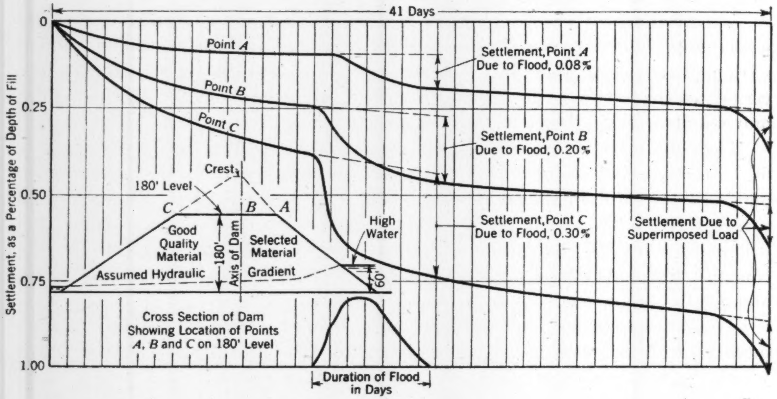

FIG. 17

1.93 ft; and down on the face of the dam, 55 ft below the crest, where the depth of fill is 215 ft, there is a vertical settlement of 2.28 ft and a horizontal settlement of 1.44 ft. The maximum vertical settlement at the crest is 0.90% of the height of fill.

Facing.—No one standard design of facing can be claimed to be best for all conditions. Each dam is its own problem.

Strawberry Dam has an apron of reinforced concrete sliding leaves over the upper two-thirds of the dam, each approximately 12 in. thick, 60 ft wide, and 135 ft long, fastened at the bottom but free to slide upon a smooth plastered surface covered with roofing paper. Over the lower one-third of the structure the concrete facing was poured directly against the dam, but not until all cracks between the rocks had been plastered to prevent the concrete from running in between the rocks. This was thought to be a measure of economy. There is no evidence that the leaves over the upper two-thirds of the dam have ever moved.

It is interesting to note that the expansion joints at Strawberry Dam have no seal. The original design called for the joints to be packed with asphalt or oakum. High water overtook the water before the seal was installed but the joints proved tight and were never packed. These joints were constructed about 2 in. wide and terminated at the back against the underlying concrete rib.

At Dix Dam concrete was poured directly against the face of the rubble section of the dam and worked in between the rocks. Vertical and horizontal expansion joints were provided. At the east abutment large differential settlements were anticipated and the spacing of expansion joints was decreased. The bottom 180 ft of water in this dam has never been emptied, but inspection at the most critical point, which is above the draw-down, after 10 yr of service indicates a relative movement of about 2 in. at the expansion joint, with some twisting. There are no open cracks in the slabs that are visible. Joints have taken all movements. There were no construction joints as each panel was completed in one continuous pour.

The writer believes that if a concrete facing is adopted it should be poured directly against the dam and between the face rock, with adequate expansion joints. Spacing of these joints should be such as to accommodate the larger settlement occurring over sections of the dam where there is an abrupt change in the depth of fill. Vertical joints should be constructed open or closed according to their position in the dam.

JOHN E. FIELD,[21] M. AM. SOC. C. E. (by letter).—The author is to be commended for bringing this newer and less known rock-fill dam to the attention of the profession, for the very practical suggestions he has made, and for suggesting dimensions based on his experience for criticism and further development and change. Although the paper is quite complete and very instructive, there are experiences among individual engineers which, if presented, would be illuminating. With the growing appreciation of the value of drainage in dams of all types, the rock-fill dam should find a wider and more general acceptance.

Assuming proper design in all cases the writer lists the three types of dam in point of economy of construction, thus: (1) The earth-fill; (2) the rock-fill; and (3) the concrete dam. All must be 100% safe because less than absolute safety cannot be tolerated.

Some designers assume too hastily that, since dumped rock assumes a natural slope, this natural phenomenon offers a perfect guide in design. This assumption may, or may not, be correct, depending on what is meant by a "natural" slope; whether it is the slope on which the rock will stop moving when dumped, or the slope on which, when at rest, the rock will start moving. Observed natural slopes are: For the lee side of sand dunes, 1 on 1.5, and sliding will start when a small quantity of sand is excavated from the foot of the slope; in rock slides composed of small flat and shell-like rock, the angle is generally less than 30°, or about 1 on 1.8; and in rock slides of large boulders the observed slope is often as much as 40°, or about 1 on 1.4. These slides were made by rock falling from cliffs which, by reason of their inertia, would develop flat slopes; also, the action of frost and the elements over long periods of time have flattened them. In excavating a bench across such rock slides or old mine dumps, or cutting through them, the side slopes of the cut are generally made much steeper than the surface slope although at present the tendency is to flatten the slope to prevent rock, loosened by frost or rain, from rolling into the cut. Too many stable and successful dams have been built with slopes less than 1 on 1.3 (see Table 1) to justify the adoption of that slope as a minimum. Although the writer does not disagree with the suggested practical 1 on 1.3 slope for rock-fills he feels that steeper slopes are preferable unless structural conditions and operations require the flatter slope. The steepest slope permissible is that at which movement would start but, as far as the writer knows, this has not been determined by research, or by experiment with different materials, placed by different methods.

---

[21] Engr.-Examiner, PWA, Washington, D. C.

The difficulty encountered in connecting the impervious facing to the abutments suggests making a temporary connection of some flexible material, such as lumber, which would last well beyond the period of settlement.

In a rock-fill dam, with all the uncertainties of a reliable, permanent, impervious facing, one must assume that water may pass into the fill and the presence of any erodible material should be avoided.

Two of the dams listed in Table 1 have failed. The Castlewood Dam, in Colorado, was washed out in 1933 by over-topping. The spillway was in the center of the dam, about 200 ft long and 4 ft below the crest at either end; the lower slope was in steps built up of large rectangular rock and then grouted. Many smaller floods had passed through the spillway and over the stepped lower slope, but in the 43 yr the grouting, never first class, had largely disintegrated, the flood of 1933 had probably loosened and dislodged some of the steps, and the material in the body of the dam was rapidly washed away. This material was composed of rock, spalls, and sand; probably the entire material from the quarry, with some of the over-burden, was used. On three occasions prior to 1904, also, piping had washed out the foundation material. After the third wash-out an earth blanket on a slope of 1 on 3 was placed up stream from the dam and was effective in preventing further trouble. The design or dimensions of this rock-fill dam were not at fault, but poor foundations and poor workmanship were to blame for the three wash-outs and the final collapse.

The Beaver Park Dam, in Colorado, has been an economic failure because water in large volume—130 cu ft per sec—passed beneath and around the dam, through the abutments. Apparently, the canyon in which the dam was built had no rock in place, either at the bottom or on the side slopes. It appears that a slide had occurred from the high cliff to the east and choked the ancient river channel, and water passing through this broken up mass of rock had eroded a new channel. After the serious leaks appeared, the bottom and east slope were drilled and grouted but, due to lack of funds, were not extended sufficiently into the old slide and the leak at present is greater than the normal flow of the stream. It has been suggested that an earth blanket be placed in the area above the dam both against it and on the hill slope to a point up stream and beyond the area of the old slide. The crest of the dam appears to have moved about 3 ft down stream and to have settled nearly as much; the rock used was rather soft and friable. In this case, a lack of proper borings and ignorance of the geological conditions are quite apparent.

Fig. 18 shows the section of a dam in which the rock is graded; such grading will probably decrease the percentage of settlement. The plan differs from those of most rock-fill dams in that the Class *A* is large rock and that Class *B* next up stream is from 3 in. to 15 in., and the next is 3 in. and smaller, with a filtering medium of sand (Class *D*) between Class *C* and the earth-fill. Classes *B*, *C*, and *D* are put through a crusher and screened. If the fill is made in horizontal lifts, it is apparent that the line of contact between the several classes of rock can be altered—made steeper or flatter as desired. The lower slope (1 on 2) seems flatter than necessary, and being flatter than the natural dump slope, probably requires some extra work in placing (see Fig. 18).

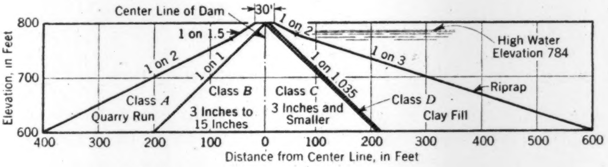

FIG. 18

Core-walls in the center of a dam are inadvisable not only on account of inaccessibility but more because the full hydrostatic pressure is at the center of the structure, leaving to that part above the core-wall the sole duty of supporting the rip-rap and the core-wall. With settlement of the structure and the raising and lowering of the water in the reservoir, changing stresses are imposed on the core, and, if it is an earth-fill, the part above the core becomes saturated, with a decided tendency to slide into the reservoir. Resultant stresses, first on one side and then on the other, tend to rupture the core-wall. A core composed of screened gravel, however, would be of benefit in lowering the line of saturation, and the rock-fill dam can be considered an extreme case in which the "core" occupies almost the entire section of the dam.

Where, for any reason, it is desirable to use all the materials from the quarries, including the generally condemned "fines," one can visualize a core of screened rock obviating any danger of lack of proper drainage in the fill.

Under some conditions gates and collapsible stop-planks can be used in spillways; for example, if the discharge capacity has been determined for a 200-yr period on a 100-yr record automatically collapsible stop-planks could be installed to meet the 1 000-yr probability. Gates placed in a spillway are generally undesirable and to rely on the watchman or attendant at the dam is dangerous; if, however, there is a power-house or factory at the dam where numerous and competent men are always at hand, gates in spillways could be tolerated.

Acknowledgment.—Fig. 18 was derived from the original plans of Oneonta Dam, in Alabama.

JOHN H. WILSON,[22] ASSOC. M. AM. SOC. C. E. (by letter).—Observation of the sandstone in a dam near Oneonta, Ala., will be of interest to those who are contemplating the use of sandstone for rock-fill purposes. By definition Mr. Galloway excludes this earth and rock-fill type; but the character of the rock and the quarrying methods are those that would be encountered at this site regardless of the type of dam.

The rock-fill design contemplated the placing of four gradings of stone.

---

[22] Dist. Representative, R. G. Le Tourneau, Inc., Peoria, Ill.

The construction plant was set up to meet the original specification of (quoting):

> "348,072 Cu. Yds. Class (A) shall be run of quarry. It is expected that 50% will be larger than one-man stone.
> "314,584 Cu. Yds. Class (B) shall be crushed stone of from 3 inches to 15 inches in size.
> "336,552 Cu. Yds. Class (C) shall be crushed stone ½ inch to 3 inches in size.
> "36,916 Cu. Yds. Class (D) shall be screenings ½ inch or less in size."

The site of the quarry is adjacent to the dam area, the elevation of the quarry floor being approximately 50 ft higher than the crest elevation of the dam. Over-burden of clay was removed by drag scrapers and carried down to a sandstone which was of decomposed character, yet too hard to excavate by such equipment. A dragline was used to remove more of the decomposed stone. Test specimens of the material uncovered were classified as "argillaceous sandstone," the bonding material being ferric oxide. Under this stone is a harder, more highly consolidated material.

Primary blasting was conducted by use of well-drill holes spaced about 15 ft on centers and loaded with an average charge of 950 lb of dynamite. The detonating agent used was cordeau.

The resulting fragmented rock was loaded by 4-yd steam shovels and hauled in 12-yd side-dump tractor wagons to a 48-in. by 60-in. jaw crusher. From the primary crusher the stone went on to a grizzly that removed the material smaller than 8 in. to a vibrating screen which made the final classification of the material. A secondary 20-in. gyratory crusher received a part of the stone that passed over the grizzly, and fed the fine material to the same grizzly and vibrating screen for reclassification.

Stone too large to be manipulated by the 4-yd shovels is reduced in size by continuous secondary drilling and blasting. The operations described have resulted in the introduction of a large percentage of fines smaller than 0.5 in. The primary blasting and secondary blasting have produced a large quantity of these fines, and the crushers have added to the total. Between 15% and 20% of the total yardage produced will screen smaller than 0.5 in. The quantity of rock broken down by blasting, to sand or fines, is so excessive that it has not been possible to load the larger stone to the exclusion of this fine material. The loads of quarry-run stone containing, by visual inspection, too great a proportion of fines have been wasted.

In order to accommodate the use of the fines produced at the screen, the thickness of the up-stream blanket of Class D rock was increased from 5 ft to 8 ft. A further effort was made to include the fine material in the dam by introducing thin horizontal blankets over the Class B and Class C rock.

Mr. Galloway has requested that discussion be directed to problems of design. The writer's purpose in relating the methods used in the construction of this sandstone rock-fill dam is to direct the attention of designing engineers to conditions that may exist in another sandstone formation similar in character to that described. In the writer's opinion sluicing of fines into the larger rocks would produce a more dense fill than has resulted in the past. This might give greater stability to the structure, but it also might prove objectionable from the standpoint of open drainage for water which seeps past the facing.

The exclusion of fines from a quarry operation in rock of this nature will increase the cost of construction. Not only by reason of rehandling, but during rainy weather the fines form a gritty mud which clogs screening equipment, resulting in serious retardation of construction operations.

The writer would suggest alternate methods of writing specifications covering construction that involves the placing of sandstone fills:

(1) Eliminate all attempt to classify the sandstone by crushing and screening, placing the run-of-quarry stone in the fill. Sluice the fine material to prevent any accumulation of fines in a local area. In order to provide a section that would be stable, both the up-stream and down-stream faces of the rock-fill would probably have slopes of 1 on 2, or flatter. The resulting increase in quantity would not necessarily mean an increase in price or cost due to the lowered unit cost of producing the fill material.

(2) If it is anticipated that a part of the quarried stone may be unsuitable for use, it seems to the writer that the basis of payment for rock-fill should be yardage in cut; or yardage in fill, plus an allowance for yardage placed in a designated waste dump. This would permit the construction engineer more latitude in his selection of suitable stone for the fill. This kind of clause in the specification should be reflected in the price bid for the work by permitting the bidder to reduce his allowance for coverage of ambiguous contract provisions.

In considering the design of a rock-fill dam with rock of questionable character, due regard should be taken of the construction problems which will influence the cost of construction and thereby affect the economy of design.

FREDERICK H. FOWLER,[23] M. AM. SOC. C. E. (by letter).—The definition of a "rock-fill dam" adopted by the author, well describes the type of structure that has reached its maximum development in the Sierra Nevada of California. It does not, however, include the many important variants of the rock-fill type that have developed elsewhere, particularly in regions where foundation conditions are more difficult and common labor cheaper than in the California mountain districts.

Even in the rock-fill structures of the Sierra there has been a rapid evolution and, in the later dams, such as Bucks Creek and Salt Springs, in California, the placed-rock sections are far thinner in relation to the greater heights, and conform more closely to the author's definition than did the earlier Relief Dam, in California. At Relief, for example, with a maximum height of only 140 ft, the combined horizontal thickness of the facing and placed-rock section at the base of the dam was 100 ft. At Salt Springs, with a maximum height of 328 ft, the adopted combined horizontal thickness of the facing and placed-rock was only 25 ft. At Relief, in other words, the base thickness of the placed-fill section was more than 70% of the total height of the dam; at Salt Springs, it was less than 8 per cent.

These designs thus tended toward a simplicity of structure, an increasing proportion of drop-fill, and a corresponding decrease in rubble fill and mortar-placed facing, an evolution that may be considered as typical of practice in the Sierra Nevada.

---

[23] Cons. Civ. Engr., San Francisco, Calif.

It will be noted, however, that no design reached the ultimate limit of the drop-fill type, namely, a complete drop-fill structure as in the Cogoti Dam, in Chile,[24] with no derrick-placed cushion. Nor have the designers of dams in the Sierra of California been driven by difficult foundation conditions, or tempted by a plentiful supply of cheap labor, to increase the proportion of derrick-laid rock or to abandon drop-fill entirely.

Drop-fill, however, has been definitely abandoned in Algeria.[25] The most recent technique in hand-placing and derrick-placing of fill and the design of facing, etc., for four large Algerian dams, is set forth in an article[26] published since the author's paper. This article gives (in convenient form and in English translation) material hitherto scattered in various publications in several foreign languages.

From a western viewpoint, the Algerian designs are notable for the care and thoroughness used in the construction of the entire main fill of derrick-placed rock of the largest sizes practicable, with the crevices well packed with smaller rock and quarry spalls. Settlement in the body of the dam is reduced to a minimum by care in placing the fill, and further reduction and equalization of settlement, due to poor foundations, are sought by the construction of thick rubble foundation slabs, on which the rock-fill rests. Under these slabs are very complete systems of under-drains. Heavy cut-off walls, provided with inspection and work galleries, run the full length of the up-stream base of the dams, and deep grout curtains at the up-stream sides of the cut-offs were used as an additional precaution against seepage. Highly specialized laminated facings, varying in detail at the several dams, are characteristic of all four structures. Although none of these dams conforms to the author's very specific definition of a rock-fill dam, they can scarcely be placed under any other general classification.

An even more specialized rock-fill structure is the Shing Mun Dam,[27] 275 ft in height, designed to supplement the water supply of Hong Kong and Kowloon. According to the description, the dam consists of five parts. Its face is a relatively thin diaphragm built of rich reinforced concrete and divided, by vertical bitumen-filled joints, into segments, so that it can stand considerable distortion without destruction; a cut-off wall is formed by an extension of the face downward to impervious rock and built of rich unreinforced concrete placed for maximum density. Back of the face of the dam and the cut-off wall is a "thrust-block" of low-grade mass concrete, resting on the surface rock and designed to transmit the water pressure to the rock-fill behind. Finally, in order to insure a uniform transmission of pressure between the thrust-block and the rock-fill, a wedge of dry sand is inserted between these elements.

[25] "Note sur le Masque en Béton Armé du Barrage de Bakhadda," by M. Drouhin, *Annales des Ponts et Chaussées,* 1935, VIII, pp. 281–291.

[26] "Algerian Dams of Placed Rockfill," by I. Gutmann, *Engineering News-Record,* December 2, 1937, p. 889.

[27] "Steep Concrete Face on Rock-fill Dam in China," *Engineering News-Record,* November 12, 1936, p. 677; also, Second Congress on Large Dams, Washington, D. C., September, 1936.

The rock-fill was hand picked and brought up in 2-ft layers sloping toward the thrust block. Drains, and inspection pits and galleries, are provided. The Shing Mun design is "a far cry" from the simple designs outlined by the author, and is probably on the border line between what may, by broadest definition, be called a rock-fill, and a composite structure of uncertain classification. It demonstrates to a marked degree the changes in a basic idea that may be brought about by vastly different costs of labor and material, in combination with more difficult foundation conditions.

Through the migratory tendency that is common to engineering designs, Algerian practice in placing fill and foundation treatment has invaded Mexico, and Chilean practice in laminated concrete facing has traveled to California.

The use of derrick-placed and hand-placed fill in the Mexican project (the Tepuxtepec Dam, on Rio Lerma, Michoacan) probably resulted from the employment of an Italian consultant, thoroughly familiar with North African practice. Its use was made economically possible by the large available supply of cheap labor. Derrick-placed fill, rubble-masonry foundation slab, drainage, and deep grout curtain follow, closely, Algerian practice, under generally similar conditions. The design of the backing for the up-stream facing, however, departs from Algerian and other practice, since it consists of a series of horizontal blocks (with inclined up-stream edges) extending back varying depths into the fill, and tending to tie the fill and facing support together. This unusual block design is merely another example of the many attempts to secure a proper adjustment of the impervious facing to the progressive settlement of the rock-fill body of the dam—one of the main problems in the successful design of this general type of structure.

What is termed the "Chilean type" of laminated concrete facing is that used on the Cogoti Dam in that country. In the article[28] describing its details, it was stated that the same type of facing was to be used on seventeen major rock-fill dams then proposed by the Chilean Bureau of Reclamation; however, according to the most reliable information now available, construction of all these dams, except the Cogoti Dam, has been postponed on account of adverse conditions in world finance, and no details are available concerning the results secured through its use on the Cogoti Dam. That structure was to be built entirely of loose fill, with slopes conforming to the angle of repose of the material used in the structure. A facing of concrete was to be poured against a gravel blanket on the up-stream slope and the laminated facing of reinforced concrete laid directly on this base slab. This plan to secure a stable and watertight structure without using any expensive derrick-laid rubble is naturally very attractive, if practicable, and it is to be hoped that a full description of the measure of success attained at Cogoti may be forthcoming.

The results attained in Chile are of particular interest, since a very similar type of laminated facing was used initially on San Gabriel No. 2 Dam, in California, and was extremely unsatisfactory, with the settlement that developed in that structure. Different methods of construction might have reduced the settlement in the fill, and with a reduced settlement the facing might have held. An answer to the question as to whether the failure of the facing was due to excessive settlement or to an inherent weakness in the laminar type of facing may be had when the results in Chile are known.

---

[28] *Engineering News-Record*, November 5, 1931, p. 725.

Selection of construction methods that will produce a fill (of either placed or dropped rock) with a relatively small and generally uniform settlement, and a type of facing of sufficient flexibility to follow such settlement in the fill as cannot be avoided, constitute two of the main problems in design. Under Algerian conditions, with relatively poor foundations and high value of water, difficulties of maintaining a tight face with large settlement in drop-fill, have led to the definite abandonment of that type of placement.

Even where drop-fill is to be used there remains either much to be learned concerning the best construction methods, or a very considerable adjustment of divergent engineering views as to what is accomplished by certain methods already generally accepted. All authorities appear agreed, for instance, that plentiful sluicing of the fill during construction will facilitate and accelerate settlement, thus making it possible to construct the final facing at an earlier date and with less fear of harmful distortion than would otherwise be possible. However, aside from the general agreement that lubrication of the larger pieces is one of the most beneficial results of sluicing, there are divergent views concerning its purpose. One description states that the purpose of sluicing is "to wash the fines into the fill," and another states with equal conviction that the purpose is "to wash the fines out of the fill." Possibly more detailed descriptions of local conditions and construction methods in these particular projects would reconcile these apparently discordant statements—in the meantime, the reader is somewhat at sea.

No more valuable contribution could be made to the discussion of rock-fill dam design than a thorough analysis of the settlement that has taken place, both during construction and after completion, in various dams now actually in operation. This is particularly true of large and unusual structures such as Dix, in Kentucky, Salt Springs, Bucks Creek, San Gabriel No. 2, and Cogoti Dams. Measurements are already available in brief form for Bakhadda Dam,[29] of the Algerian derrick-placed type; these measurements show not only the settlement that took place during the initial filling of the reservoir, but also the elastic recovery that occurred upon emptying the reservoir.

It would also be interesting to know the settlement that has been recorded, and the action of the welded-steel facing, in the El Vado (gravel-fill) Dam, which, so far as the writer knows, is one of the largest steel-faced fill dams now (1938) actually completed.

The difficulties that have arisen in designing concrete or other permanent facing that will conform without rupture to the considerable initial settlements of very large rock-fill dams now commonly constructed, warrant favorable consideration of timber facing; this, although of relatively short life, will last well through the early period when settlement in the rock-fill is largest and most rapid. By the time that it becomes necessary to renew the timber facing most of the settlement will have taken place, and far greater freedom may be used in the selection of facing design.

---

[29] *Engineering News-Record*, December 2, 1937, p. 892, Fig. 5.

I. C. Steele[30] and Walter Dreyer,[31] Members, Am. Soc. C. E. (by letter).—The following discussion of Mr. Galloway's excellent paper will be principally confined to the subject of the design and settlement of Salt Springs Dam, in California, the principal design features of which are described by Mr. Galloway. Reference is also made to a paper[32] by O. W. Peterson, M. Am. Soc. C. E., which includes a description of the construction methods used in building the dam, and to an article,[33] "High Rock-Fill Dam with Jointed Concrete Face," by I. C. Steele, which includes a plan of the dam, a table showing slab thicknesses and reinforcing, and a table of elevations and offsets used in laying out the vertical and horizontal curvatures of the up-stream face. Fig. 19, a view of the up-stream face shortly before completion of the rubble facing, shows various features and elevations pertinent to this discussion and to the aforementioned references.

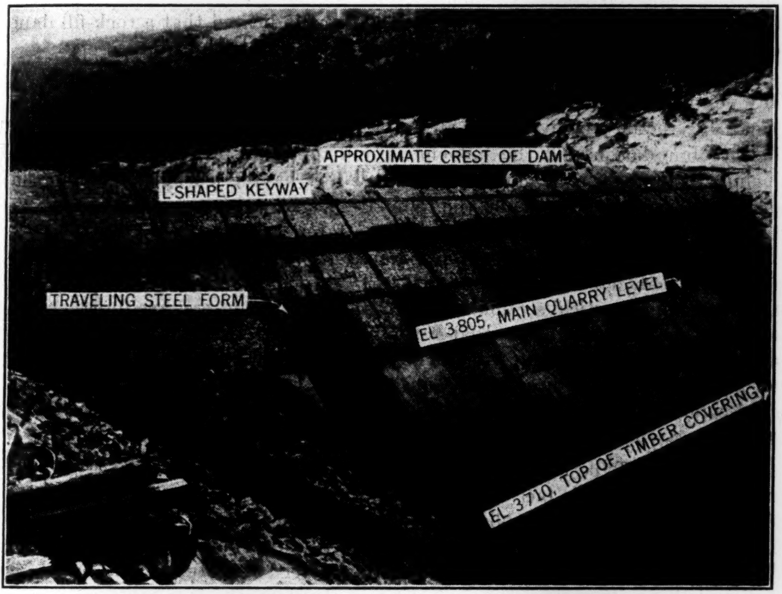

Fig. 19.—Up-Stream Face During Construction, Salt Springs Dam

A brief summary of the controlling features of design and construction should be sufficient for the purpose of this discussion.

Factors Influencing Selection of Rock-Fill Type of Dam.—Several factors influenced the decision to build a rock-fill type of dam at Salt Springs. The dam site offered a choice between the rock-fill and concrete gravity types. Preliminary estimates indicated a saving of about $2 000 000, including indirect and overhead charges, for the rock-fill structure. The intended height, 328 ft above general foundation level, did not greatly exceed the height of the successful Dix Dam in Kentucky. Unlimited quantities of good quality rock were readily available for quarrying at desired elevations. The construction of a large capacity spillway, separate from the dam, was feasible. Studies of available data, and experience with other dams, indicated that a rock-fill dam of the desired height could be built and operated with the utmost safety.

[31] Asst. Chf., Div. of Civ. Eng., Dept. of Eng., Pacific Gas & Electric Co., San Francisco, Calif.

[32] *Proceedings*, Am. Soc. C. E., August 1930, p. 1319.

[33] *Engineering News-Record*, Vol. 104, p. 92.

Consideration Given to Settlement in the Design Assumption.—Settlement at any point on the face was estimated to be the vector sum of the vertical settlement due to the weight of rock in a vertical column of rock extending from face to foundation and the movement due to water pressure acting on an inclined column of rock normal to the face and having a length equal to the distance between the face and the foundation. An arbitrary value was given to the coefficient of settlement or compaction for this purpose.

Design of Face.—Details of face design are shown in Fig. 20 which also shows methods subsequently adopted for the repair of cracks and joints. A face concave in vertical section was selected to insure compressive forces acting toward the fill in the event that settlement differed greatly from the design assumption. A convex face might be pushed outward especially if there was an abrupt change in direction. Consideration was given to several methods of designing the concrete face for the dam. The several designs considered and the reason for eliminating some and selecting the one are:

(1) Sliding Type Face.—This design consisted of a single thickness of slab supported on a rubble face which has been made smooth with concrete and on which asphalt has been applied. The concrete face would be separated from the rubble and, theoretically, would be free to move independently from the body of the dam. This plan was discarded after some study because it was believed that with water pressure acting on the dam, the face could not move as it was intended to, because construction inequalities and settlement during construction would make the supporting face quite irregular. There also was objection to the relatively slim column to withstand compressive forces developed by movement of the dam, particularly when water pressure was not acting on the face.

(2) Laminated Face.—This type was never given serious consideration because of the desire to make the face quite substantial. A laminated face cannot be anchored successfully to horizontal keyways unless the keyways, in turn, are supported on rigid struts extending upward from the cut-off in the plane of the face.

(3) A Monolithic Slab.—A slab of substantial thickness, and with the concrete worked well back into the interstices of the first layer of dry rubble, was built so the face would have sufficient rigidity to withstand compressive forces resulting from settlement of the rock-fill on which the face was laid. During the early stages of construction the interstices in the exposed surface of the first layer of rubble were left open. This method was later changed and all large openings, and many of the smaller ones, were chinked in order to prevent

undue waste of concrete and to lessen the possibility of movement of fresh concrete from the slab proper into voids in the rock section as the traveling steel forms were moved ahead.

Joints in Face.—Consideration was given to a continuously reinforced concrete face, but one consisting of panels about 60 ft square, with joints along the periphery, was selected partly because of anticipated movement of the fill from each bank toward the center of the canyon in a direction parallel to the axis of the dam, which movement would induce very heavy compressive stresses in the face, and also because studies showed that if the dam settled in the manner and to the degree which was estimated, the stresses would be so great that the face would fail structurally. The adopted type is essentially a number of panels approximately 60 ft square with copper water-stops in the construction joints. Horizontal joints (see Fig. 20) are designed without an elastic filler, so the downward compressive forces can be transmitted directly from one panel to another. Inclined joints are made with a 1-in. thickness of elastic material to permit some movement parallel to the face. Other dams have placed two joints at each inclined rib, but one was considered sufficient for this dam. The copper seal was designed to have sufficient strength to withstand a separation with a maximum head of 4 in. without exceeding usual working stresses. Horizontal keyways were made triangular in shape to avoid overhanging rock during construction. They also served as walkways and work platforms during this period.

Settlement of Face.—The only data available with respect to settlement of rock-fill dams was for the settlement of the crest. The settlement obtained under the design assumptions described in the foregoing indicated that the greatest movement that would be likely to occur after the face was poured was in the lower elevations of the dam. Therefore, reference points were set in the concrete at a corresponding corner of each panel and the movement of these reference points was measured at frequent intervals during the first three years after setting and once each season thereafter.

Fig. 21, with Table 2, shows selected settlements at each measuring point for indicated periods. The extent of vertical, horizontal, and diagonal movement of any point may be obtained by scaling. Initial readings are plotted along straight lines at elevations which are averages of the two end points in each row. Joint opening or closing, as measured along the line of points in Row *H* and caused by lateral movement of the rock-fill, is shown at the top.

The maximum movement in a direction normal to the face was 5.41 ft at Point *D*, Station 4+60. Of this amount, 1.41 ft occurred prior to the first filling of the reservoir, and 4.0 ft occurred during and subsequent thereto. The latter value approximately represents the normal settlement caused by water pressure. Settlement almost equal to the foregoing occurred at Points *C* and *D*, Stations 5+20 and 5+80.

Fig. 22 shows settlements at various measuring points along the face for four vertical sections parallel to the river. The vertical distances between spillway crest level and points of maximum measured settlements for the several sections of fill which exceed 150 ft in height average about 60% of the corre-

* Reservoir rose only to maximum elevation 3 910, in 1931.

As mentioned previously, the settlement at any point on the face was assumed to be the vector sum of two components, one the vertical settlement due to weight of the fill in a vertical column of rock extending from the face to the foundation and the other movement due to water pressure acting on a column of rock extending from the face to the foundation in a direction normal to the face and having a length equal to the distance between the face and the foundation.

The greater part of the first component occurs while the fill is being made and prior to the construction of the concrete face and, therefore, is not an important factor in affecting the structural behavior of the slab. The settlement that occurred after the concrete face was installed has been carefully measured and analyzed. Maximum settlement of the crest under the first component and for a height of dam of about 330 ft has been nearly 2 ft. The vertical settlement at any other point on the face due to weight of rock only should vary as the square of the vertical distance from the face to the foundation. This component of settlement at any point on the face, therefore, can be expressed as $2.0\left(\frac{h}{H}\right)^2$, in which h = height of point above the foundation and H = maximum height corresponding to the settlement of 2.0 ft.

If the coefficient of settlement could be taken as a constant, the vertical displacement due to water pressure could be expressed by the factor,

$$S = \frac{P\,h}{K} \quad\text{.........................(1)}$$

in which P is the vertical component of water pressure and K is a "modulus of settlement" similar to Young's modulus for an elastic substance. Owing to storage operation it is not always possible to measure the settlement of all points on the face of the dam. At the time of the latest complete observation

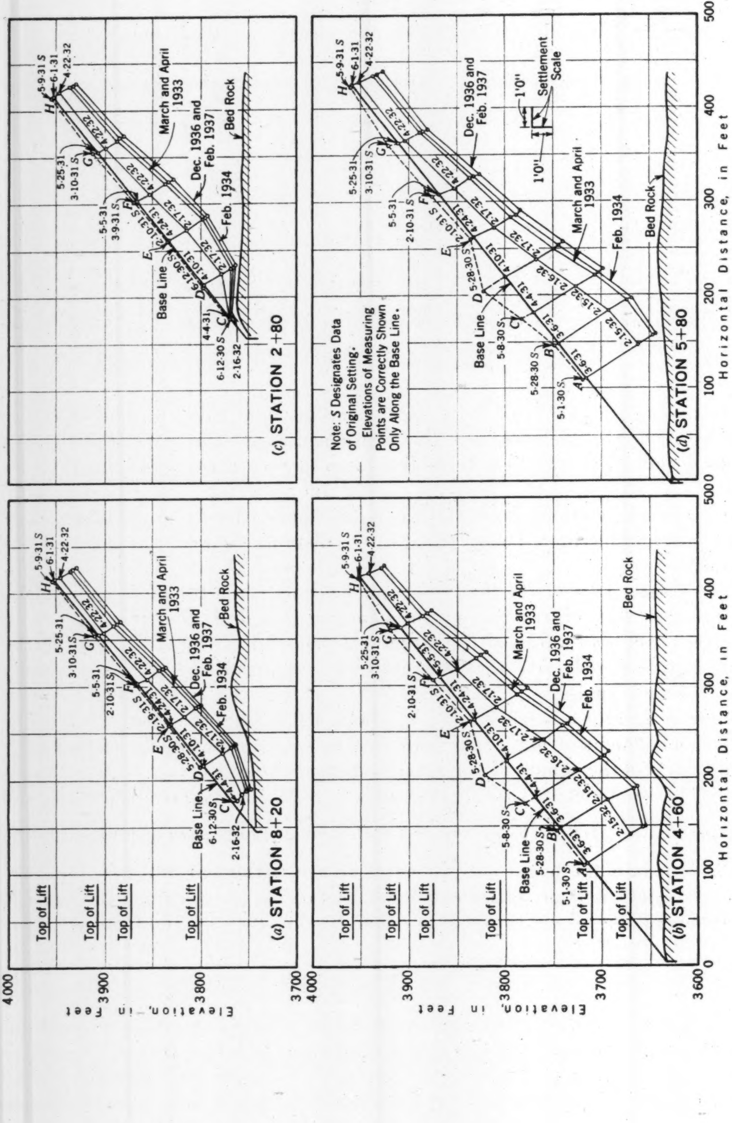

FIG. 22.—PROGRESSION OF SETTLEMENT OF SELECTED SECTIONS, SALT SPRINGS DAM

the settlement of the crest was 1.75 ft. If the vertical settlement due to the weight of the fill only at other points is deducted from the total settlement by using the formula, $1.75\left(\frac{h}{330}\right)^2$, the resulting amount would be due to water load only, and if the foregoing assumptions are valid, the factor, K, can be determined.

The result of this determination is shown graphically in Fig. 23, which has lines of equal resistance to vertical settlement under water load. Each line has the same value for the "modulus of settlement"; hence, the total settlement due to water load can be computed by Equation (1).

It will be noted that around the periphery of the canyon, the modulus has values of 300 000 to 400 000 lb, but is considerably higher at the center of the canyon above Elevation 3 800, which was approximately the main quarry level. Below this elevation the fill was well seasoned, so the settlement was relatively less there than in other parts of the dam.

Effect of Settlement on Concrete Face.—During construction and prior to pouring the face it was found that the settlement of the fill made it somewhat of a risk to construct the rubble face too far above the elevation of the concrete face. Tremendous forces are transmitted from the loose fill to the more rigid rubble face and in a few cases massive granite stones 4 to 5 ft thick at the bottom cracked, or were slightly displaced, under these loads when the rubble wall was carried approximately 100 ft above the concrete face. It is best to let the fill be well seasoned before placing either the rubble or the concrete in order to reduce these stresses to a minimum. In one case these forces were so great that a concrete slab about 2.5 ft thick and with two layers of reinforcing steel, split in the plane of the upper layer over a triangular shaped area 50 ft long and having a maximum width of 17 ft. Similar action occurred over several other small areas in the immediate vicinity.

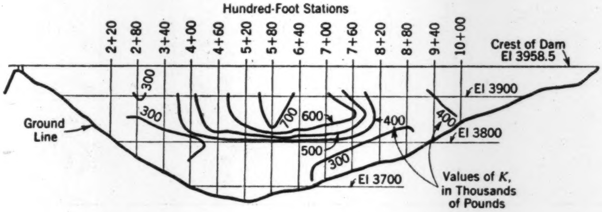

FIG. 23.—VERTICAL PROJECTION OF FACE OF SALT SPRINGS DAM, SHOWING LINES OF EQUAL RESISTANCE TO SETTLEMENT UNDER WATER LOAD

Settlement under water load demonstrated that greater flexibility was necessary adjacent to the canyon walls and in future work the design would provide for three or more joints about 5 ft apart instead of only the one joint at the cut-off wall which was used at Salt Springs. A number of small cracks developed in this region, some of which are shown, after repairs, in Fig. 24. With few exceptions these cracks lie within 60 ft of the abutments and most of them lie within a zone about 20 ft wide and roughly parallel to the cut-off wall.

The limits of this zone are approximately 10 ft and 30 ft away from the cut-off wall. As many as nine cracks, closely spaced, appear at some elevations. The uppermost crack of this nature does not extend closer than 60 ft, vertically, below the crest of the dam. Cracks vary in width from hair-line dimensions to a maximum of 0.5 in. in one or two instances. Most of the cracks were about $\frac{1}{16}$ in. wide. It has been necessary to chip out and fill these cracks, the method of repair being shown in Fig. 20. These repairs were made in 1932, 1933, and 1935, at a total cost of about $15 000, a nominal sum in view of the magnitude of the dam. At present writing (1938) leakage charts indicate that few additional cracks have developed since last repairs were made.

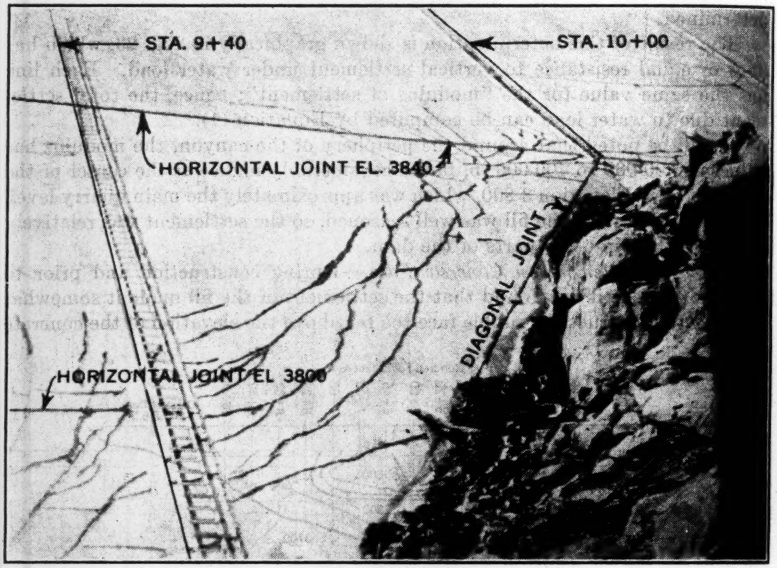

FIG. 24.—VIEW SHOWING CRACK REPAIRS IN CONCRETE FACE, SALT SPRINGS DAM

Movement of the fill toward the center of the canyon caused eight of the inclined joints to close completely, three to such an extent that the compressive stress caused spalling in the upper levels. It was necessary to reconstruct partly three of these joints. The uppermost panel at Stations 3+40 and 4+60, and the two upper panels at Station 5+80 were repaired in the manner indicated in Fig. 20 at a cost of less than $4 000. In future work of this nature the space between adjacent panels will be increased to 2 in. or more in those joints that are likely to be compressed.

Thickness of Rubble Face.—Mr. Galloway mentioned two items given particular consideration when the thickness of the rubble face was being determined for the design, namely, that water pressure indicated that the thickness should be greatest at the bottom; and settlement under vertical load, being greatest at the top, indicated that the rubble should be thickest at the crest, so that a uniform thickness finally was adopted. In the light of the experience at Salt Springs during construction and since, the writers, who participated in the original discussion and agreed to the selection of the uniform thickness, now believe that the thickness near the bottom should be greater than at the crest and that the thickness at the crest could, in a well constructed dam, be less than was used at Salt Springs. The reason for this opinion is that most of the settlement of the crest occurs before the rubble wall and concrete face are constructed, so it is not necessary to have a heavy rubble wall at that level to protect the concrete face. The maximum total movement of the face occurs at about one-third the height of the dam and the greatest differential movement occurs at the bottom and around the periphery of the face near the canyon walls. The greatest protection, therefore, should be had at these critical points.

Furthermore, as brought out by the late D. C. Henny, M. Am. Soc. C. E., in his discussion[34] of Salt Springs Dam, the local sliding factors in the rock adjacent to the up-stream face are high in relation to the coefficient of friction of the rock. In the case of a dam like Salt Springs, the sliding factors at the bottom level are 77% at the face, reducing to about 60% at the back of a 25-ft thick rubble wall (thickness measured normal to the face). It appears desirable in this part of the dam to have a rubble wall with the rock well keyed together so that horizontal movement need not be resisted by frictional forces entirely. This prompts the writers, in the light of all the foregoing factors, to suggest, in the interest of consistent design of high rock-fill dams, a rubble face having a thickness normal to the face of 10 ft at the crest and increasing about 5 ft for each 100 ft of height. It may be advisable to go even further than this by arbitrarily increasing the thickness of the rubble face for some distance out from the canyon walls, as this area of the face is almost certain to develop some cracks.

Conclusions.—It is believed that the crest settlement at Salt Springs Dam is less in proportion to its height than the measured settlement of any other structure of similar cross-section. In the opinion of the writers, the principal reasons for this and for the successful performance of the structure throughout are:

(1) Adoption of essentially natural slopes of loose rock-fill for the up-stream and down-stream faces;

(2) Construction of the loose fill, with quarry-run rock of good quality granite;

(3) Placement of loose fill from high lifts (75 ft or more) resulting in a well compacted fill;

(4) Liberal sluicing of loose fill during placement operations;

(5) Delayed construction of a well-built dry rubble section to form a cushion of reasonable thickness between the impervious membrane and the loose fill; and,

(6) Delayed construction of a monolithic type reinforced concrete jointed impervious membrane of substantial proportions on the up-stream face of the dam.

---

[34] *Proceedings*, Am. Soc. C. E., August 1930, p. 1325.

F. KNAPP,[35] ESQ. (by letter).—The art of designing rock-fill dams, as developed during nearly a century of progress, and based on the experience gained by American engineers, is contained in this valuable paper. Abroad, notably in Algeria, several dams of the type discussed by the author have been built by French engineers, following, in general, the design principles stated in the paper. The innovation introduced consists in vibrating the rock-fill for the purpose of keeping down the voids and, therefore, diminishing the settlement of the structure. The Bakhada Dam, for example, with a height of 45 m (147.6 ft), an up-stream slope of 1 on 0.86 at the top, 1 on 1 at the bottom, and 1 on 1.25 for the down-stream slope, showed a horizontal deflection at the crown of 0.30 m (11.8 in.) and a vertical settlement of about the same magnitude, or 0.7% of the height. The rock-fill consisted of blocks with an average weight of 5 metric tons, resulting in 32% of voids. Increasing the size of the blocks to 10 tons reduced the voids to 26% as evidenced by the dams of Bon-Hanifia and Grib.

The Bakhada Dam, designed originally with a double slab of reinforced concrete and only vertical joints, the lower one with a thickness of 30 cm (11.8 in.), suffered only the small settlements mentioned, with the result that the lower slab, with the reservoir filled, showed neither cracks nor displacements. The drainage amounted to 15 liters per sec (0.5 cu ft per sec) diminishing to 0.1 liter per sec after the second slab was built. It is interesting to note that the space below the joint of the upper slab is being drained by means of small channels.

The concrete slabs of rock-fill dams should be made as elastic as possible in order to be able to follow the settlements of the rubble cushion, and the speed of placing the rock-fill should be kept down to an economic limit for the purpose of allowing the fill to settle under its own weight. Vibrating the fill and sluicing contribute to a possible increase of the speed of construction.

RALPH J. REED,[36] M. AM. SOC. C. E. (by letter).—The successful service of the typical rock-fill dam depends upon the maintenance of an impervious facing supported by the up-stream slope of the fill. Although small settlements can be provided for in the design, any considerable settlement of this facing may result in such failure of it as to affect seriously the structure of the dam, or at least to result in excessive leakage. It seems to the writer, therefore, that such provisions should be made in the design and such measures should be taken in the construction of a rock-fill dam as will result in the larger part of the dam's settlement taking place before the permanent facing is completed. In accomplishing this result it is obvious that the character of the rock used is of primary importance. The selection of rock that is hard, sound, and does not readily disintegrate, is emphasized by the author. The usual quarry operation results in the production of rock varying considerably in size, so that, without resorting to measures which increase the cost of production, it is usually not feasible to produce or to select rocks of fairly uniform size; and it is questioned whether such selection may be at all necessary. It is believed that a grading from larger to smaller rocks, with the rejection of very small rocks and spalls, and the placing of the fill in low lifts extending completely along the length of the dam, from abutment to abutment, will be advantageous in accomplishing the larger part of the settlement of the fill as construction goes forward, and in diminishing the settlement which is to be expected when the full water load is taken and continues. Even if great care is taken to reject fine material —earth, spalls, and dust—at the quarry, a certain amount of rather fine material will be present in the fill due to chipping and breaking of the rock during transportation from the quarry and handling in the fill.

---

[35] São Paulo, Brazil.

[36] Cons. Engr., Los Angeles, Calif.

Sluicing the dumped rock in order to wash this finer material into the fill and to prevent its accumulation in any particular zone, is important; and there may also be a lubricating effect from sluicing, resulting in somewhat better settlement of rocks into position upon their supporting rocks. The performance of San Gabriel Dam No. 2 of Los Angeles County Flood Control District is illustrative in this regard. This high rock-fill dam was built in 1932-1933, the fill being made "in the dry," without sluicing. The specifications provided that the rock used in the main fill should be:

> "* * * a well-graded mixture of sound, angular, quarry-run rock, forty (40) per cent of which shall vary in weight from quarry chips to one thousand (1000) pounds, thirty (30) per cent shall vary in weight from one thousand (1000) pounds to three thousand (3000) pounds, and thirty (30) per cent shall vary in weight from three thousand (3000) pounds to fourteen thousand (14000) pounds."

The rock was not to contain more than 3% of total weight of quarry dust. Although the placing of the laminated concrete slab facing of the dam was delayed until the fall of 1933, when the fill was practically completed, the sluicing effect of very heavy rainfall during the following winter months produced such large settlement of the fill and accompanying deformation of the up-stream face of the dam that the facing was seriously damaged. Subsequent sluicing during the summer of 1934 through openings drilled through the slabs resulted in further settlement, but to a lesser degree. The condition of the facing was such, however, that its complete removal became finally necessary; and the dam has since been provided with a laminated timber facing. It is believed to be clearly indicated that generous sluicing of the fill during the construction of this dam would have resulted in such settlement at that time as would have made possible the building of a concrete face and its maintenance without the failure that occurred.

F. J. SANGER,[37] ASSOC. M. AM. SOC. C. E. (by letter).—In his able summary of the historical development of rock-fill dams, the author shows that large rock-fill dams are rare outside the Western States, and it is thought that the record of such a dam in Australia which partly failed, and the measures taken to remedy the fault would be of interest. Rupert Grenville Knight[38] describes the case fully, and only a very brief précis of his paper is given.

---

[37] Head, Dept. of Eng. and Building, The Lester School and Henry Lester Inst. of Technical Education, Shanghai, China.

[38] "The Subsidence of a Rockfill Dam and the Remedial Measures Employed at Eildon Reservoir, Australia," by Rupert Grenville Knight, *Journal*, Inst. of Civ. Engrs., March, 1938.

The Eildon Reservoir and Dam were completed in 1927. The dam, including a spillway section (734 ft), is 3 529 ft long. It partly failed in 1929, after the water level had been lowered 46.5 ft, and remedial measures required six years and cost the equivalent of $2 000 000.

The core-wall is of reinforced concrete, 137 ft high, and from 6 ft to 2 ft thick; it is reinforced with 0.5-in. bars at 12-in. centers in grids and has expansion joints at 50-ft intervals. The site is composed of variable shales with some slates and sandstones, with about 20 ft of clay above for two-thirds of the length of the dam. On the up-stream side of the wall a mass of clay was deposited, of base thickness from 27 ft to 37 ft and with a batter of 1 on 6. The rock-fill is of material similar to the bed-rock and weighs 90 lb per cu ft. The slopes were 1 on 2.

Failure began with a slip, exposing the core-wall as well as deflecting it for a length of 700 ft in the middle of the dam, and then extended to a 1 200-ft width when the top 26 ft of the wall was exposed and the fill moved 55 ft into the reservoir; subsidence continued slowly for some weeks afterward, and the maximum wall deflection was 4 ft 8 in., causing many serious cracks. Borings showed that the clay had been squeezed out into the fill. In the discussion of the paper several theories were advanced for the failure, and the most probable reason seems to have been a clay slip in the foundation material.

Remedial measures included adding rock-fill on the toe to prevent sliding and extra deflection of the wall, repair of cracks, drainage, and the reconstruction of the spillway, outlets, etc. In addition, the frictional resistance of the down-stream side was increased by adding rock-fill and by under-drainage. An additional 700 000 cu yd of fill were needed, making the total in the dam 2 000 000 cu yd.

C. S. JARVIS,[39] M. AM. SOC. C. E. (by letter).—Examination of rocky bars intruding into or across stream channels will disclose the fact that these are rock-fill dams with slopes naturally adjusted to withstand over-flow. Many of the rapids prevailing in torrential stream channels are only the down-stream faces of such natural barriers. As might have been expected, such sites have been chosen for intakes of power or other diversion canals. Favoring such locations are the ease and effectiveness with which the current can be deflected by merely piling stones to form wing-walls, then stowing brush, straw, or litter to close the interstices; both initial construction cost and cost of maintenance were reduced thereby.

The development of the basic idea of rock-fill dams may be traced through many centuries of agricultural practices, particularly in relation to terracing on hillside slopes. Dry rubble walls with pronounced batter provided the required stability; rock spalls or stony soil strewn against the inner face of the wall formed both a matrix to hold the stones in place, and a porous screen to retain the fertile soil while permitting adequate drainage.

As the need became apparent for conserving nearly all rainfall in place on these terraces, to bridge over the periods of deficiency so far as practicable, the terrace walls were raised and trench-like pockets similar to those provided by modern contour listing were formed to increase water storage capacity. To prevent wholesale loss of stored water through overtopping and drainage from one basin to another, the terraces were divided transversely into sections of moderate length, each with considerably greater capacity than that ordinarily required to take care of local rainfall and resulting pondage.

---

[39] Hydr. Engr., SCS, Dept. of Agriculture, Washington, D. C.

Other progressive steps in the use of rock-fill dams provided mill ponds and stock-watering ponds, and larger storage basins behind either combination rock-fill and earth dams, or rock-filled timber cribs. Where suitable soil for earth-fill was scarce or required long haulage, and durable rock was abundant, the natural result was a puddled core in an earthen fill, retained between loose rock shoulders, consisting of either dry rubble walls or more voluminous fills of quarry-run stone dumped to natural slope.

There are in existence to-day, in widely scattered locations, within the United States and neighboring countries, examples of minor rock-fill dams with either earth cores or earth aprons to serve as the relatively impervious element. Among those stock-watering, farm, mill, or wild-life ponds located in regions subject to accelerated erosion, sedimentation has reduced storage volume and necessitated expensive maintenance or enlargement from time to time—or ultimate abandonment. Many of these ponds antedate the legislation requiring approval by the State Engineer's Office; some even date from early colonization by Europeans; but they have served as important factors in the settlement and development of American frontiers.

The writer has never ceased to wonder at the volume of dry rubble and other stone masonry construction, backed by rock-fill, or by a combination of earth and rock, along the network of navigation canals, logging channels, dams, and spillways of the last century or more, including the canal constructed by George Washington around Great Falls of the Potomac River, near Washington, D. C. Some of these structures are still in service, and many others could be restored to working condition at moderate cost, if sufficient demand arose for such uses as they originally served. However, it seems improbable that the nation will ever revert to such extensive projects to serve slow methods of transportation, now that rapid transit seems to be the main objective and has been so widely attained.

There is ample opportunity for future use of low rock-fill dams on minor projects. For greater storage depths the factors of safety should likewise increase, because of the danger of high velocities and sudden widespread destruction as a result of overtopping or failure from any other cause.

Advancement in the art of dam construction has apparently awarded preference to some form of cohesive integral masonry structure for great storage depths. In order to displace masonry structures from what is admittedly their own province, as may doubtless be advisable at times, proponents of the competing type should be required to show overwhelming advantages in first cost, maintenance, or both, with no sacrifice of necessary safety factors. Small differences should be waived in favor of the type which could withstand over-flow and could continue to function even in cases of catastrophic floods, far beyond the probable limits as contemplated by the design.

The position of the water-tight element of a rock-fill dam may be anywhere within the limits of the up-stream face, in the writer's opinion (see Fig. 25), provided the design of cross-section conforms to the position so chosen. The pavement, diaphragm, or apron used as a water-seal may or may not be parallel to the up-stream surface. A core-wall, if installed at all, should stand vertically with either stepped or battered faces to account for thinning toward the top. Certainly, a well-constructed core-wall with its footings properly established in bed-rock, and the superstructure well reinforced against cracking, sandwiched between the up-stream third and the down-stream two-thirds of the entire fill, should be a satisfactory water-seal, if properly encased or cushioned against irregular concentrations of pressure (as from large, angular boulders during the inevitable settlement and compaction of materials). Likewise, an equal volume of masonry or durable mastic material, spread over the greater area presented by the up-stream slope; or well-fabricated sheet metal in a similar position, but protected from both corrosion and abrasion by suitable covering, may satisfactorily serve the same purpose, and may both permit and require inspection, repair, or replacement more frequently than the core-wall.

The author has contributed much of both historical and scientific interest relating to the design of rock-fill dams and to fundamental principles, considerations, and requirements influencing the final choice of structural type for a given location. His definition of rock-fill dams departs somewhat from that accepted in general practice, in that it would apparently exclude such structures as depend on either puddle cores or earth aprons as the impervious face. Thus, his definition would exclude the Castlewood Dam (Table 1, Item No. 5), which had an "earth embankment added to upstream face, 8 feet wide at crest with 3:1 slope faced with 12-inches of riprap."[40] Likewise the Avalon Dam, in New Mexico, both the Milner and Minidoka Dams, in Idaho, and the Zuni Dam, in New Mexico, listed as "rock-fill,"[41] would have been excluded by the author's restrictive definition. Moreover, it would exclude a number of rock-fill dams with puddled earth cores described by the writer[41] in 1915.

---

[40] American Civil Engineers' Handbook, Fifth Edition, 1930, p. 1547.

[41] "Provo Reservoir Company's Irrigation Project," by C. S. Jarvis, *Engineering News*, August 26, 1915, p. 394.

Whether the impervious element is in the form of timber, metal plate, masonry, or dense plastic material used, respectively, as facing or as diaphragm core, cut-off, or up-stream apron, a structure dependent on a loose rock-fill for stability seems to qualify as a rock-fill dam. When the earth-fill for either the core-wall or the up-stream apron comprises a volume nearly equal to that represented by the rock-fill, it would appear fitting to include mention of this material in the designation, as "earth and rock-fill dam." However, when the earth apron represents only a minor percentage of the total volume, and is placed mainly to increase the resistance to seepage through bed-rock and abutment formation, by adding to length of travel and thus reducing the pressure gradient, the structure may still be designated as a rock-fill dam. There would be fully as great justification for mentioning the timber, the steel plates, the concrete facing, or the masonry core-wall as to mention the earth-fill used for the same specific purpose, namely, as a seal against seepage.

L. R. East,[42] M. Am. Soc. C. E. (by letter).—Owing to his association with an inquiry into the causes of the partial failure of a large rock-fill dam at Eildon Reservoir, Victoria, Australia, in 1929, the writer has found this paper of particular interest. This dam comprised a rock-fill embankment extending for a distance of 2 525 ft across a comparatively wide valley to a mass concrete spillway of the side-spillway type providing for overflow along a weir section, 682 ft long.

In the river section abutting the concrete spillway, the embankment is approximately 140 ft high, and the rock-fill is founded on bed-rock which is composed of fairly hard metamorphic rock with sandstones and slates dipping almost vertically and with strike diagonally across the line of the dam. Across the river flats, the rock-fill was placed directly upon the natural surface, with from 22 to 24 ft of clay and gravel wash and about 2 ft of sand overlying the bed-rock. On this side of the valley the rock available for fill was shales and mudstones of a less durable character, with bands of slate.

For water-tightness a central vertical core-wall of reinforced concrete was provided, with a clay wall on the up-stream side to assist in staunching any possible leakage through the concrete. This wall varied in thickness from 6 ft at bed-rock (into which it was keyed to a depth of 5 ft) to 2 ft at crest level. The clay wall, of very stiff puddle trafficked with horses and drays during construction, averaged about 30 ft in thickness at the natural surface.

The rock-fill was quarried on both ends of the dam, loaded by hand on trucks (the stone being broken to "one-man" size) and side-tipped into position. The stone from the river quarry was comparatively hard and durable, but that from the other quarry was soft, easily crushed, and weathered rapidly.

Owing to financial difficulties, construction was slow, and the embankment was not brought to its designed height until practically twelve years after the commencement of the fill. At no time, however, did construction actually cease. There was time, therefore, for considerable settlement and consolidation during this period, particularly as water was stored to as high a level as possible during construction.

FIG. 26.—TYPICAL CROSS-SECTIONS, EILDON RESERVOIR

Fig. 26 shows the plan and typical cross-sections of embankment and spillway as designed, the basic data being as follows:

Description		Quantity
Height of bank above river bed, in feet		140
Height of spillway above river bed, in feet		123
Length of core-wall, in feet		2 300
Length of spillway crest, in feet		682
Storage capacity, in acre-feet		306 400
Area submerged, in acres		8 000
Length of waterway, in miles:		
Delatile River	11.5	
Goulburn River	10.5	
Total		22
Length of water frontage, in miles		70

Fig. 27 shows a typical cross-section of the embankment as completed in 1927 when the reservoir was filled to its full capacity of 306 000 acre-ft for the first time in August of that year. It was not drawn down very far the next year and in the spring of 1928 it was again filled to capacity, the water flowing over the spillway to a depth of 4 ft 2 in. in October. The irrigation season then resulted in a heavy demand on the storage and in four months, to April 1929, the reservoir was drawn down to the extent of 50 ft.

FIG. 27.—TYPICAL CROSS-SECTION OF EMBANKMENT, EILDON RESERVOIR, AS COMPLETED IN 1927

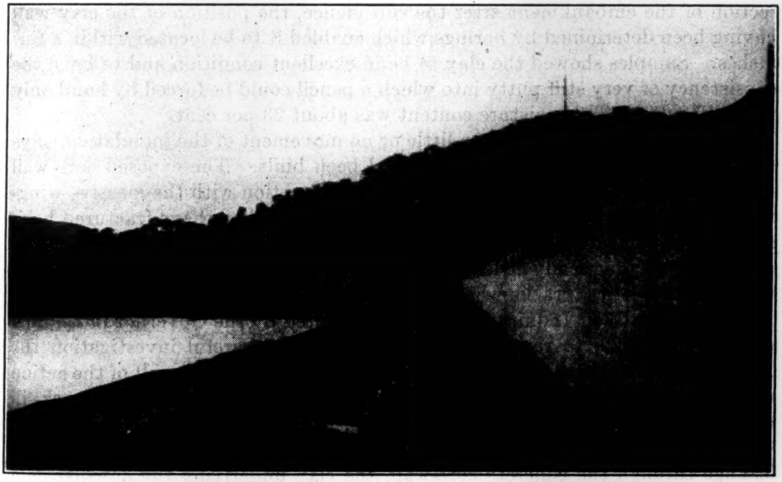

FIG. 28.—VIEW OF EXPOSED CORE-WALL, JUNE 16, 1929

At that stage, without warning, the rock-fill on the up-stream side of the core-wall subsided suddenly and the concrete core-wall itself was exposed over a length of about 1 200 ft to a maximum depth of 26 ft (see Fig. 28). The greatest subsidence occurred against the core-wall itself which was deeply scored or scratched by the rock-fill sliding against it. The exposed top of the core-wall showed deflections of as much as 4 ft 8 in. in lengths of 400 ft and 800 ft originally constructed as straight lines.

Fig. 29 shows the line of the core-wall as constructed, its position in September, 1929, after the subsidence, and its position in 1933, since when movement has been very slight—the movement during the 5 yr since 1933 being less than 2 in. at the point of maximum deflection. Fig. 30 shows a typical cross-section of the embankment after the subsidence, the position of the clay wall having been determined by borings which enabled it to be located within a few inches. Samples showed the clay to be in excellent condition and to have the consistency of very stiff putty into which a pencil could be forced by hand only with difficulty. The moisture content was about 23 per cent.

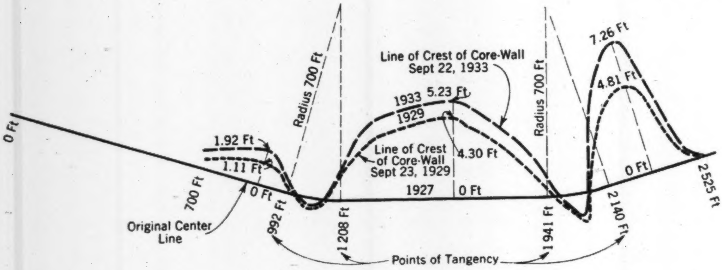

FIG. 29.—DIAGRAM SHOWING LATERAL DEFLECTION OF CORE-WALL, EILDON RESERVOIR

There appeared to have been little or no movement of the foundation clays and gravels upon which the rock-fill had been built. The exposed core-wall showed several vertical cracks, notably at the junction with the massive wing-wall at the river end, and later investigation showed it to have fractured horizontally for some distance along its junction with the rock foundation. There was, however, practically no leakage through the horizontal crack and very little through the vertical cracks which were fairly easily staunched.

The Eildon Weir Inquiry Board was appointed by the Governor in Council on May 24, 1929, to report on the failure. After careful investigation the Board concluded that the subsidence had arisen directly as a result of the action of the clay wall; that the clay had acted as a stiff fluid and pushed the rock-fill out into the water; and, at the same time, had exerted great pressure down stream causing the concrete core-wall to deflect. Although there was little leakage through the concrete core-wall, the clay underlying the down-stream rock-fill was very wet, and as the rock-fill was much lighter than an earth bank (being only 90 lb per cu ft) there was considerable apprehension as to the risk of the entire structure failing by sliding of the down-stream part of the bank. The remedies suggested by the Board were:[43]

FIG. 31.—TYPICAL CROSS-SECTION SHOWING ADDITIONAL ROCK-FILL PROPOSED BY BOARD, EILDON RESERVOIR

All the remedial measures proposed by the Board have been completed at a cost of £A380 000 (Australian pounds = \$1 500 000), approximately £A206 000 (\$825 000) was for the placement of additional rock-fill, and £A36 000 (\$144 000) for the drainage of the foundation under the down-stream section of the embankment. The remainder of the expenditure was on outlet works and spillway.

Regular observations have been made to detect bank movements or deflections of the core-wall, as well as of outflow from the drainage system; and there has been little movement since the completion of the remedial works in 1933. Fig. 32 shows the dam after the completion of the remedial works.

It might be mentioned that the total leakage through the entire structure (in which there is an area of 280 000 sq ft of core-wall) does not exceed 50 gal per min, three-fourths of which comes from one definitely located small fracture at the junction of the core-wall and the outlet tunnel.

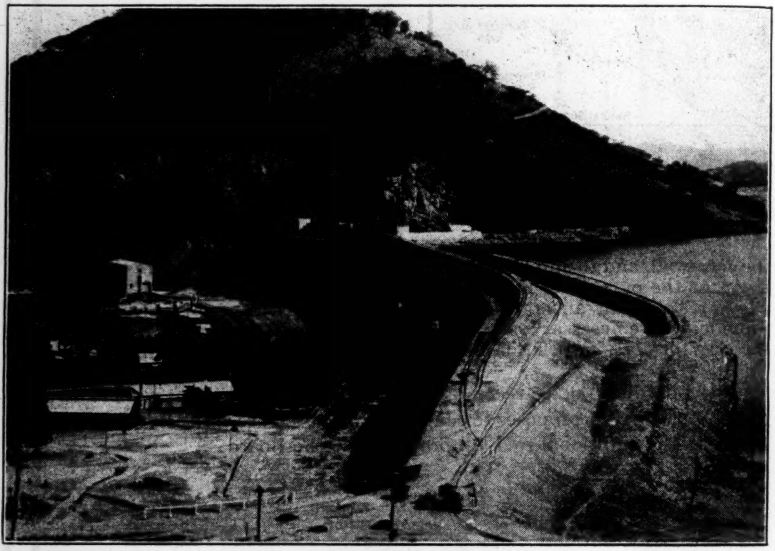

FIG. 32.—VIEW OF EILDON RESERVOIR AFTER REMEDIAL WORKS HAD BEEN COMPLETED, FEBRUARY, 1936

The writer is in complete agreement with the principles of design indicated by the author, departure from which was undoubtedly responsible for the failure at Eildon. The dam was not founded on rock, much of the material of the fill was unsuitable in that it was likely to crush and disintegrate, and the up-stream half of the embankment was made a liability instead of an asset by placing the impervious element in the center of the dam. Experience at Eildon shows that the use of a thick blanket of puddled clay, loaded with rock to protect, and confine it, might have serious consequences unless steps are taken to provide for the enormous pressures exerted by clay in the mass.

A rock-filled dam very similar in design to that at Eildon was constructed at Melton, Victoria, on the Werribee River, in 1916, and has given very little trouble. The embankment of this dam, however, was constructed of harder and more durable stone (basalt from the spillway excavation) and was founded on a rock foundation in a comparatively narrow gorge, so that the resistance against sliding of the up-stream part of the rock-fill embankment would be much greater than in the case at Eildon Reservoir.

A comprehensive description of the failure at Eildon and of the remedial measures to the embankment, spillway, and outlet works, has been published by Mr. R. G. Knight.[44]

FRANCISCO GOMEZ-PEREZ,[45] ASSOC. M. AM. SOC. C. E., AND MIGUEL JINICH,[46] ESQ. (by letter).—The very complete paper presented by Mr. Galloway on the design of rock-fill dams is based on the historical development of this type of structure. Limiting the scope of the historical summary he presents details of the construction of various dams of the rock-fill type that have been built during the last half century, mainly in the western part of the United States.

Any type of structure must necessarily be adapted to the conditions prevailing in the region where it is to be built and the rock-fill type of dam is no exception to the rule. Conditions in Mexico make low-cost labor available and, at the same time, make equipment that is generally imported a high-cost item of the construction project. These two conditions combined have influenced the development of the rock-fill type of dam in Mexico. In general, the trend has been toward using smaller rocks than would have been the case if mechanical equipment could have been used to a greater extent.

As a result of the use of smaller rocks that necessarily have a larger percentage of voids, other parts of the structure have also been affected and, therefore, the size of the panels that constitute the up-stream slab has been greatly reduced in comparison with the size generally accepted in the United States. Furthermore, and considering the possibility of seismic disturbances, a laminated type of slab has been included in one of the Mexican rock-fill dams completed in 1933. Other elements of current practice in Mexico are presented in this discussion.

General Considerations.—In sites that are far away from roads and railroads, for which the transportation of manufactured products, such as cement, steel, and timber, is very expensive—as well as those sites where such manufactured products are relatively expensive, but where labor is relatively cheap—the most economic type of dam is generally that in which the engineer can use to maximum advantage the materials found on the site. Such is the case of earth and rock-fill dams, and the combination of both. This explains why the rock-fill type has been very advantageous for many sites in Mexico. The Mexican National Commission of Irrigation has made comparative studies of various types of dams for several sites and has adopted the rock-fill type; and it has been built successfully both from the economic and from the technical point of view.

---

[44] "The Subsidence of a Rockfill Dam and the Remedial Measures Employed at Eildon Reservoir, Australia," by R. G. Knight, *Journal,* Inst. C. E., March, 1938.

[45] Chf., Control Div., Designing Dept., National Comm. of Irrig., Govt. of Mexico, Mexico.

[46] Chf. Designer, Designing Dept., Mexican National Comm. of Irrig., City of Mexico, Mexico.

The following rock-fill dams have been completed in Mexico: Charcas Dam, 49 ft high, in the State of Guanajuato in 1933; Taxhimay, 137 ft high, and Madero, 153 ft high, both in the State of Hidalgo (the former in 1934 and the latter in 1938); San Ildefonso Dam, 189 ft high, in the State of Querétaro, designed in 1937 (under construction in 1938); and the Tepuxtepec Dam, 126.5 ft high, in the State of Michoacán, in 1934.

Foundation Requirements.—There is no doubt that sound, durable rock is the ideal material for the foundation of a rock-fill dam, as for any other types; but, in certain cases, it is necessary to use this type at sites where the rock may not be so sound. In the latter case, the site should fulfill the following requisites:

(1) Even when saturated, the material on which the dam is to be founded must be capable of resisting all the load transmitted to it both by the fill and by the hydrostatic pressure when the dam is filled, without any appreciable settlement. The saturated condition must be considered even if it is assumed that all precautions must be taken to prevent filtration, by means of cut-off walls and an up-stream slab.

(2) The material must resist chemical solution and all tendencies to become eroded.

The Charcas Dam had been designed as a gravity structure, but for economic reasons (and mainly due to the character of the foundation rock) it was decided to change the design to a rock fill. The rock was a rhyolite in an advanced state of disintegration that did not furnish the necessary support for a gravity dam; but it complied with the aforementioned requirements for a rock-fill dam.

The Taxhimay Dam (shown in Fig. 33) was a small rock-fill structure that had been built in 1918. When it was taken over by the Commission, in 1927, to be used as a reservoir for one of its irrigation districts the engineers decided to enlarge its capacity by increasing the height of the structure, and it became necessary to study the problem relative to including the old structure within the section of the new one. The old dam was 61 ft high, had been built originally without the necessary precautions for cleaning the river bed perfectly, and the material that had slid down the side-hills had not been completely removed before the original dam was built. The old dam consisted of a loose rock-fill with a down-stream slope of 1 on 1, and up-stream slope of 1 on 2. The impermeable part consisted of a cement-bound masonry zone 6.5 ft thick at the bottom and 1.33 ft thick at the crown, and resting directly on the loose rock-fill. The defects of the original design, together with the foundation defects, caused severe settlements that almost made the structure fail.

In designing the new dam, for the purpose of raising the water surface elevation to a new height of 134 ft it was necessary to remove all the silt and loose materials and to deposit the new fill on the sound solid rock. This structure includes the old loose rock-fill dam and has been finished and in service since 1934 with very satisfactory results.

At the site of the Madero Dam, in the State of Hidalgo, the rock is also sound. It has been classified as a very resistant rhyolitic tuff in the river bed but the resistance gradually diminishes as the elevation increases. When the preliminary design was being prepared, it had been decided to use an arch dam, but on account of the poor resistance of the rock at the higher elevations in the site it was decided to build a rock-fill dam.

TYPICAL SECTION

Fig. 33.—Cross-Section of Taxhimay Dam, State of Hidalgo, Mexico

The Material.—Almost always the material for the construction of rock-fill dams comes from near-by quarries. It may be of volcanic origin, it may be granitic, or it may be either sandstone, or limestone, but the main requirement is that it be sound.

The size of the rock used varies from about 4 in. to the largest size that is feasible to move with the equipment available. It is always better to use rocks of the largest dimensions possible, and to limit the volume of small fragments such as quarry spalls, to a quantity that partly fills the voids and is not so large as to prevent easy drainage through the rock mass, nor to favor local concentrations of the material which, because of the larger percentage of voids, may cause important settlements.

It is evident that water-jets make it possible to use a larger proportion of this quarry-run material, depending on the methods of placing the loose rock-fill. It is also evident that water causes the material to be slushed into the voids between large rocks, without endangering the easy drainage of the mass. It may be possible even to distribute the large rocks better by the use of water-jets.

Cross-Section.—The down-stream slope adopted in the dams built by the Commission has been 1 on 1.4, slightly steeper than the natural average slope for the loose rock-fills. Of course, this slope may vary within limits depending on the size of the rock used and mainly on the degree of arrangements obtained for the rock-fill.

In the aforementioned dams, in view of the low cost of labor, and in order to give them a better appearance, a "finish" layer has been built on the downstream slope. In the Charcas Dam it consists of the formation of steps, and, in the others, in leaving a more or less smooth rubble masonry surface. This finish improves the appearance of the dam greatly at a relatively low cost.

The main function of the hand-placed rock-fill zone is to serve as a semi-rigid transition section between the outermost layer and the loose rock zone, as the latter is subject to uneven settlement. It gives the outer layer a smooth surface that corrects the irregularities of the loose rock-fill. It also stabilizes the slopes by using them as retaining walls to hold back the loose rock-fill making it possible to use such steep slopes as 1 on 0.75. Such an arrangement (which is recommended by several authorities) seems to offer some economy, but in Mexico this has not been the case on account of the limitations of the equipment generally available for moving rocks of large dimensions.

The original design of Charcas Dam included an up-stream slope of 1 on 0.75 with a zone of hand-placed rock. This zone varied in thickness from 61 ft at the base to 6 ft at the top. After construction had begun it was realized that it was not economical to build the zone of hand-placed rock-fill, which was almost a dry masonry, with 20 to 25% voids. An economic comparative study was made to determine the actual cost of a zone of hand-placed rock-fill, fulfilling all the aforementioned specifications, and the cost of making the slope less steep, adopting a ratio of 1 on 1.25. This was the average natural slope for a rock-fill that would not require perfect work to make it act as a retaining wall. It needed much less thickness, therefore, thus becoming reduced to a nearly superficial layer placed on the slope only for the purpose of supporting the slab.

The dam was built with this slope (1 on 1.25) without any particular attention being paid to the hand-placed rock zone, thus making it possible to obtain additional economy in the pouring of the concrete, because it was placed without the use of forms, and by using a concrete with s slump of 0.5 in. to 1 in.

The difficulties that were met in the construction of the hand-placed rock-fill zone at the Charcas Dam were attributed to the lack of equipment and it was on that account that Taxhimay Dam was built with an up-stream slope of 1 on 0.75 as designed, with a thick mass of hand-placed rock-fill (in which large rocks were used) but with a small percentage of voids. The construction of this type was considered economical because of the possibility of using steam-shovels, derricks, and railroad spurs that were available for its construction. However, it was also difficult to use this design since its cost threatened to be very great if it was to be built in accordance with all the required specifications; and, furthermore, it also required unusually high-class and permanent inspection. As a result of the foregoing experience the up-stream slope for the Madero Dam was made 1 on 1.2.

For the San Ildefonso Dam the slope adopted was 1 on 1.4 both up stream and down stream. When construction was begun it was foreseen that a large portion of the material available in the quarries would be wasted, because it consisted of alternate layers of sound basalt and very finely crushed basaltic breccia. This condition dictated a change in the design (see Fig. 34) and it was decided to build the dam with a central zone to include the material that otherwise would have been wasted; the specifications required that this material be perfectly wetted and rolled, which seems to be in accordance with the tendency shown in the latest rock-fill dams built in the United States, such as Salt Spring and San Gabriel No. 2, both in California.

FIG. 34.—CROSS-SECTION OF SAN ILDEFONSO DAM, NEAR SAN JUAN DEL RIO, STATE OF QUERETARO, MEXICO

An exception to the aforementioned examples of slope is found in Tepuxtepec Dam, with slopes of 1 on 0.7 up stream and 1 on 0.8 down stream. This entire dam is practically a dry massonry structure with a percentage of voids varying between 20 and 30. It was built by the Southwest Mexico Power Company, and required masonry labor as skilled as would have been required if it had been built as an ordinary masonry structure. Large rocks transported by cableway were used, each individual piece being hand-placed; and all the voids were filled with spalls.

The cost was greater than would have been the case if the dam had been built with flatter slopes and with most of the rock dumped in place (except a thin zone of hand-placed rock to support the up-stream slab). The type was adopted because of the danger of earth shock in that region. It must be stated that the results obtained at the Tepuxtepec Dam have been splendid, and that no settlement has been observed.

Water-Proof Element.—Modern practice requires the construction of a water-proof element for rock-fill dams that consists of a rather thin concrete slab placed on the up-stream slope. In some rock-fill dams, a steel plate has been used instead of the concrete slab, but this has been the exception.

There is no doubt that the most important problem encountered in the design of the impermeable slab is to make it as water-proof as possible, and, at the same time, sufficiently flexible to follow the unavoidable settlements that occur in this type of dam, without excessive cracking. Just as difficult of solution are the problems relative to the joint at the place where the flexible slab connects with the rigid cut-off walls. It is also important to foresee the changes in length to which the slab may be subject due to changes in temperatures.

The type of slab built in sections, separated by elastic joints, seems to be the most satisfactory solution, and it is the one that has been adopted by the

Mexican National Commission of Irrigation. The up-stream element of the Taxhimay Dam consists of panels about 15 ft wide by 24 ft to 32 ft long, measured on the slope and connected by copper-plate contraction joints. The steel reinforcement placed on the center of the slab does not cross the vertical joints, but it does cross the horizontal joints in order to act as articulating units in the respective columns or strips in which the slab as a whole is divided (see Fig. 35).

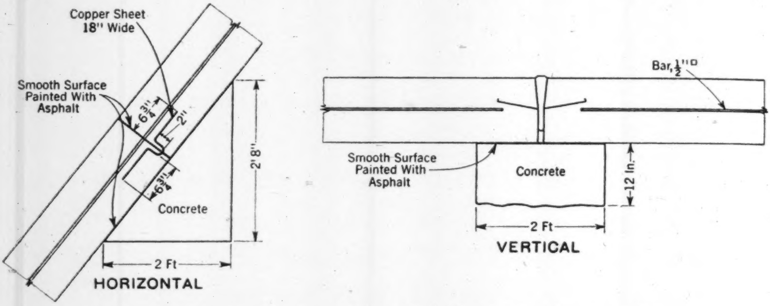

FIG. 35.—TYPICAL SECTIONS OF PANEL FACINGS, TAXHIMAY DAM

Whereas the tendency in the United States seems to be to divide the up-stream slab into rather large panels (about 50 ft or 60 ft square), the Mexican National Commission of Irrigation has adopted much smaller panels, even smaller than the ones used at Taxhimay, in order to make them more flexible, at the same time keeping them within economic limits.

At Madero Dam the panels were built 13 ft wide and 16 ft long and at San Ildefonso Dam they were made 10.5 ft by 17.5 ft. For these two structures neither the horizontal nor the vertical reinforcement crosses the copper-plate elastic joints. The size of the panels was determined by selecting the size of the pre-fabricated forms that would be simplest to build and move around on the slope.

As an exception to this rule Charcas Dam may be cited, in which, because the structure was low and long, and was built by a method that guaranteed a minimum of settlement, the slab was placed in alternate strips about 15 ft wide, leaving only construction joints through which the reinforcing steel placed in the central part of the slab was extended. The dam was inspected about two years after it was built, and it was observed that the joints had opened slightly, forming very fine cracks which, however, do not endanger the stability of the dam.

To make the up-stream slab even more flexible, in some dams it has been built in the form of thin slabs or layers of concrete placed one on top of the other so that the joints are staggered. The most interesting example of this type in Mexico is the Tepuxtepec Dam, in which two layers were used, each being 14 in. thick at the base and 10 in. thick at the top. The slabs were built in 50-ft strips, continuous from the river bed to the crown, and the joints between strips on the upper layer were provided with a copper, water-tight seal (see Fig. 36).

An improvement in this laminated type was also used at the Cogoti Dam in Chile. It is believed that the idea is fundamentally sound; but the cost is rather high and it is justified, therefore, only in special cases where important settlements are expected or where there is a possibility of earth movements, such as is the case at Tepuxtepec Dam, in Mexico, or at Cogoti Dam, in Chile.

Thickness and Reinforcement of the Up-Stream Slabs.—The up-stream slabs in the dams built by the National Commission of Irrigation (see Fig. 37) are designed with a thickness of 8 in. at the top, with a batter of $\frac{1}{8}$ in. for every 40 in. measured downward along the up-stream slope. The reinforcement is designed for temperature variations and consists, in general, of a centrally located grid of rods placed in the center of the slab.

FIG. 37.—TYPICAL SECTIONS OF CONCRETE FACING

The slab is placed directly over the facing of the hand-placed rock-fill, taking care, however, to fill all the apparent hollow spaces with spalls so as to obtain a nearly smooth surface as a bed for the concrete face, thus preventing the mortar from seeping into the voids. The slab is attached to the rock-fill by means of 6-in. dowels, 3 ft to 4 ft long, one end of which is hooked. The hook is embedded in a concrete block; that is, it is left within the hand-placed rock-fill zone; the other end projects from the facing, and is also made into a hook that is left within the slab and tied to the steel reinforcement. These hooks are also used to hold the forms in case they are used for pouring the slab. Furthermore, in order to give the slabs a better support, steps or berms about 15 in. to 18 in. wide are left on the facing. Those steps are very convenient for the use of workmen and help to build the slab in such a way that its upper part fills the step as shown in Fig. 37.

Bottom Joint.—To design the joint at the connection of the flexible slab with the rigid cut-off wall is another problem that requires careful consideration. At Madero Dam, the joint was made flexible by means of two copper sheets and a layer of asbestos felt (see Fig. 38(*a*)). This same type of joint (see Fig. 38(*b*)) has been specified for the San Ildefonso Dam.

(*a*) MADERO DAM (*b*) SAN ILDEFONSO DAM

FIG. 38.—TYPICAL DETAILS AT CUT-OFF WALL

Placing Rock-Fill.—The more or less horizontal layers of a rock-fill are constructed by dumping the material. The height of such layers has varied between 6 ft and 12 ft (as in the case in Charcas Dam) to between 18 ft and 24 ft in the more important structures, such as Taxhimay and Madero. It is believed that the use of thinner layers tends to create a more uniform distribution of the rock; and, furthermore, by placing some of the rocks by hand, settlement is reduced quite considerably because the individual particles have a more uniform bearing pressure, one on the other. Deep layers require a more careful classification of material, a condition that is undesirable, because the large rocks roll downward, whereas the smaller ones remain on top. The use of water-jets makes deeper layers possible and tends to produce a better arrangement and a more compact rock mass.

The results obtained by the Mexican National Commission of Irrigation in building dams in rather thin layers and with a slight arrangement of the rock through the entire section, have been very satisfactory.

Conclusion.—The purpose of this discussion has been to present additional information that might not be easily obtainable and that is of interest to engineers connected with the design and construction of rock-fill dams, mainly with the intention of showing how economic conditions influence both the design and the methods of construction.

In accordance with Mr. Galloway's desire that discussion be directed to matters of design, special reference has been made to the use of small rock fragments and also to the use of small concrete panels hung on narrow berms in the water-proofing element; the writers are in agreement with other conclusions of Mr. Galloway's paper.

J. D. GALLOWAY,[47] M. AM. SOC. C. E. (by letter).—It is gratifying to note that a number of engineers have found time to discuss this paper and to contribute valuable information. It was to be expected that differences of opinion would develop, but it is to be noted that the discussion refers mostly to details rather than to the basic elements of design.

The statement that rock-fill dams should consist of a loose fill with slopes on both faces closely approximating natural slopes, with an impervious facing on the up-stream side between which and the rock-fill there should be placed a cushion of dry rubble, was not questioned. In this feature it may be assumed that there is unanimity of opinion. No one advocated placing a core-wall in the center of the dam, as experience has shown that the center of the cross-section is not the place for the impervious element.

There was some discussion of the definition of a rock-fill dam. The writer purposely restricted the definition as given, although that is a matter of opinion. Dams have been built with an earth section, supported on the down-stream side by a rock-fill. It would seem that such a dam is really an earth-fill. The resistance to the water is taken by the earth-fill in accordance with the design of that type of dam, and the rock-fill below is little more than earth of larger grains. It is sufficient for the purposes of the paper to limit the discussion to dams as described.

Mr. Pearce gives a good reason for making the up-stream slope approximately the natural slope of the rock-fill. Steeper slopes have been used, but in all cases, it was necessary to retain the loose rock in place by carrying up the dry rubble at the same time. This was done in the earlier dams, but the up-stream slopes of recent dams have rendered this procedure largely unnecessary. The suggestion was made that the horizontal joints might not be in compression, due to the natural shrinkage of the concrete in setting. This condition might obtain for a time, but it is believed that the settlement of the rock will proceed at a rate greater than the concrete will contract, thus placing the concrete in compression at the horizontal joints.

Among other points mentioned by Mr. Muckleston, he suggests the possibility of using puddled clay loaded with rock as the impervious element. It is the opinion of the writer that nothing of the nature of clay should ever be used in a rock-fill dam. When wet, as it would be, the clay will moisten and will slide from its position. Any rock loaded on top of the clay will be squeezed into it and will cause undue settlement. The same objection may be made to any form of asphalt concrete for the impervious element, as suggested by Mr. Muckleston. Although it is flexible, it will tend to flow under pressure and, in time, will lose its life from contact with water or under the influence of the sun's heat.

---

[47] Cons. Engr., San Francisco, Calif.

Mr. Paul refers to the English Dam and asks how it happened to be destroyed. Of this, the writer has no information except that given by the late A. J. Bowie,[48] M. Am. Soc. C. E. The general opinion was that the initial failure of the dam was caused by dynamite, as there was an active contest by different mining companies for water on the Yuba River at that time. However, the failure may have been due to the decay of the log cribs within the structure.

Mr. Floris calls attention to the fact that on an inclined face the weight of water adds to the stability of the dam. It was the writer's intention to convey the same idea, a fact that is common to all dams where the impervious element is next to the water. It was so expressed in the paper (see heading, "Design: Cross-Section") where the sliding factors are given and the water load included as a vertical force that acts by increasing friction to resist the horizontal component tending to slide the dam. In stating that rock-fill dams resist water pressure by their weight only, it was intended to mean that anything of the nature of arch or cantilever action, such as may be present in masonry dams, is not possible.

Dean Morris, in his interesting discussion of the paper, draws attention to the possible effect of earthquakes upon a rock-fill dam and suggests the possibility of large and unequal settlements taking place when the dam is shaken by the waves. Earthquake effects may be of two different kinds. Practically all earthquakes are tectonic; that is, they are caused by an actual rupture of the earth's crust, that may or may not extend to the surface of the ground. Differential movements along the earthquake rift may be large. In the California earthquake of 1906 the maximum differential movement along the San Andreas fault was about 22 ft and the maximum vertical movement, about 3 ft. It is obvious that a dam of the type under discussion would be badly broken if situated on the rift, especially if built with any form of facing mentioned in the paper, providing the movement took place under the dam. It is more than probable that the dam would be destroyed. Earthquake rifts, as a rule, are not single cracks in the earth, but there is usually a zone that may be of a width up to half a mile or so, where, in the past, the earth has been subject to crushing and movement. On account of the crushing of the rock, earthquake rifts or valleys are usually the site of streams where reservoirs are required for storage. The Coast Mountains of California, including the San Gabriel Range, are of this type where numerous earthquake rifts are found. It is the writer's firm opinion that rock-fill dams should never be built in such places. The type does not lend itself to the inclusion of a movable joint such as the one built on the splendid masonry dam for Pasadena, Calif., on the San Gabriel River.

The other earthquake effect mentioned by Dean Morris is that of the earthquake waves that move outward from the rift and which are of sufficient energy to shake a large part of the earth surface with sensible effects. It is true that such waves might cause some settlement in a rock-fill dam. Two factors determine the magnitude of the effects. One is the intensity of the waves and the other, and more important, one is the nature of the foundation material upon which the dam rests. There has been no case that has come to the writer's knowledge where a rock-fill dam has been close to the origin of the waves.

---

[48] *Transactions*, Technical Soc. of the Pacific Coast, Vol. II.

In the California earthquake of 1906, the Sierra Nevada was shaken, but the waves were dampened by the granite core of the mountains. There were several rock-fill dams in the mountains subjected to the waves (Items 1, 2, 3, 10, and 11 of Table 1, among others) but no damage was reported on these dams. They were situated about 120 miles distant from the earthquake rift on the San Andreas fault. It is believed that the behavior of the earth dams located close to the fault line will convey some information of the behavior of a rock-fill dam. A description of the earthquake effect on several earth dams is given in the report to the Society by the Committee on the Effect of the Earthquake on Water-Works Structures.[49] With a few minor cracks, the dams were uninjured, and the same is true of the large concrete dam of the Crystal Springs Reservoir, situated within a few hundred feet of the fault line.

The foundation material is of the utmost importance in determining the movement of a dam in an earthquake. The amplitude of the earth movements may vary from less than 1 in. in solid rock to as much as 12 in. in loose alluvial soils saturated with water. As the rock-fill dam should only be built on solid rock, or material that approximates solid rock, the dam will not be subjected to much movement. In practically all instances of rock-fill dams that have come under the writer's observation in the Sierra Nevada, the foundation material is granite.

The settlements cited by Dean Morris, of fills on alluvial soils, mine dumps, and débris on steep mountain sides, do not represent the situation of a rock-fill dam located on bed-rock between two canyon walls. Mine dumps are usually found on side hills or in valleys with a cover of soil of some thickness. They are of small-sized rock, mixed with fine material. They would probably be shaken by an earthquake and some settlement would likely occur. The same is true of the miscellaneous débris on a mountain side that might be disturbed in such cases. The small earth dam that failed at Santa Barbara was located on an alluvial soil and was undoubtedly badly shaken, as the earthquake rift passed close to the dam.

It is the opinion of the writer that properly built, rock-fill dams, situated in mountains where a solid rock foundation is available, will not be distorted to a dangerous extent. The loose rock, when in place, is difficult to displace, excepting possibly on the down-stream face. This opinion is based upon the nature of the structure, the behavior of earth dams in an earthquake, and the fact that such dams as have been subjected to earthquakes have not been injured. However, the subject is an important one and the questions raised by Dean Morris are very pertinent. Until more information is obtained, the subject must remain an open one.

Mr. Peterson's statement regarding the rock used at Salt Springs Dam agrees with the idea that the writer desired to convey when the statement was made that individual rocks of fairly uniform size are desirable. More than one-half the rock was somewhat over 10 tons in weight; the excess fines were wasted, and as most of the fines that reached the dam were sluiced into the interstices, the rock that forms the main part of the dam was of fairly uniform size. It is a matter of description. The writer must differ from Mr. Peterson in the use of water in sluicing. When rock from the quarry is dumped into the dam, the small rock and fines will accumulate at the top. Merely to allow water to run into the mass will not carry the fines into the dam as well as to have a stream of water from a nozzle under pressure directed against the mass. The water will then break up the fines and force them into the rock. If this is not done, the fines will accumulate as a layer and will not be properly sluiced into the dam. The writer agrees that the volume of water is very important. In addition to moving the fines to position, the water acts as a lubricant, assisting in the necessary settlement.

---

[49] *Transactions*, Am. Soc. C. E., Vol. LIX (December, 1907), p. 245.

The data, given by Mr. Howson, of three important dams with which he was connected, are of value as indicating methods of construction and the resulting settlement. It should be noted that the vertical settlement of Dix Dam, after eleven years, is slightly less than 1% of the height, which represents an excellent fill.

Mr. Harza raises an important point regarding the adaptability of a rock-fill dam to be used to create head for a power plant. On account of the nature of the rock-fill dam, repairs to the facing are generally necessary, whether the facing is of wood, concrete, or steel. This makes it necessary to draw down the reservoir. The writer is in complete agreement with Mr. Harza that the rock-fill dam is not a satisfactory type to be used for the purpose of creating head for a power plant.

In practically all dams of the rock-fill type, the reservoirs formed by the dam are used for storage only, the water being drawn from the reservoir to augment the low-water flow of the stream. At Salt Springs there is a relatively small hydro-electric power plant that operates by the flow of the stream when the reservoir is full or when water is being drawn from storage. However, the real function of the reservoir, at an elevation close to 4 000 ft above sea level, is to provide water for a chain of power plants on the river below the reservoir. Below the plants, the water is used for irrigation. Sabrina and South Lake Reservoirs (Items 13 and 14, Table 1) also provide water for a chain of power plants, after which it is used for irrigation. The reservoirs are at elevations close to 9 000 ft. Bucks Reservoir, at Elevation 5 160 above sea level, performs the same function for power and irrigation. Some of the reservoirs designated in Table 1 are used for irrigation. It is believed that rock-fill dams, in general, should be used to form storage reservoirs only.

Mr. Huber has described in detail the timber facing of the Sabrina and Hillside or South Lake Dams on Bishop Creek. These dams emphasize the merits of timber facing. On the dams as originally built, there was only a thin layer of dry rubble. The timber facing conformed to the settlement of the loose rock-fill without damage and when the facing was replaced, after twenty years of service, the new timber facing was placed against a fill in which the major settlement had taken place. The new facing may be expected to serve for many years.

Mr. Fowler has added some interesting data on rock-fill dams in regions outside the United States and has given some comment upon the evolution of the type in California. Mention is made of the Relief Dam in this connection. Relief Dam can hardly be cited as illustrating one step in the evolution of dams in California. It was designed by the Consulting Board with a section different from the one built. There was no need for the large section of dry rubble, and as the work was done after the Board was no longer employed, it represented only the ideas of men unfamiliar with California practice. The evolution of the type used in California begins, as stated in the paper, with the dams on the Yuba River, notably, the Bowman Dam, which was built over thirty years before Relief Dam. In the evolution of the type, the principal change has been to abandon the rubble facing of the down-stream slope and to increase the thickness of the rubble on the up-stream slope. The face slopes of recent dams have also been made with flatter slopes. At Relief, the major advance was the introduction of a concrete face.

The Cogoti Dam, in Chile, was mentioned as the one where the facing was laid directly on the loose rock-fill without an intermediate cushion of dry rubble. The Sabrina Dam, built over twenty years previously, was substantially of this type, the facing being of timber resting on a thin layer of rubble that was little more than an arrangement of stones to a uniform surface. It is illustrated in the paper, and additional information may be found in Mr. Huber's discussion.

The behavior of the laminated facings of the Algerian dams throughout the years will be of considerable interest. Contrasted with the California dams, the design of which is based upon the experience of over sixty years, the Algerian dams represent a radical departure. The writer may be allowed to express doubt regarding the permanence of laminated facings built of asphalt concrete, especially where it is necessary to spray the face with water during hot weather. It might happen that on some warm day the water spray will be omitted.

It may be questioned whether a citation of the design of dams built in different parts of the world should be given comparable weight with those dams which have had a considerable life history and in which time has been given to develop such defects as may occur during service. The dams cited by Mr. Fowler, in Algeria, Chile, and in China, are of recent construction. Information regarding their behavior during a few years of service will be of interest and may form the basis for conclusions differing from the ideas held when the dams were designed.

Messrs. Steele and Dreyer have contributed, in their excellent joint discussion, the most important data on the settlement of a large rock-fill dam that has ever appeared; that at Salt Springs Dam. The measurements extend over the five years of the life of the dam and (what is of great value) the measurements of settlement apply to areas of the dam face below the crest. It should be noted that the settlement under the combined rock weight and water load is not a maximum at the crest but is found on the slope of the dam. Settlement due to the weight of the rock occurs progressively during construction and will continue for years after the dam is placed in service. It is difficult to obtain the cumulative effect by direct measurement. The settlement under water load can be determined as stated in the discussion. Above the level of the main quarry (Elevation 3 805), there was a fairly close agreement between the calculated settlement when the design was made and the measured settlement. Below that elevation the settlement was considerably greater than that assumed. It may be doubted whether any exact calculations can be made, as so much depends upon the nature of the rock and the methods used in the construction. However, the theoretical treatment is of value as indicating what may be expected at any time when the crest settlement is known or assumed. In time the crest settlement will increase and the face of the dam will tend to straighten.

The necessity for additional thickness of rubble at the bottom and on the sides of the canyon walls is well stated, as is also the connection of the concrete face to the cut-off wall. The statements represent the experience of the engineers who have been charged with the care of the dam. The writer is in agreement with the conclusions expressed in the discussion.

Mr. Sanger has presented some data on the failure of the Eildon Dam, in Australia, and Mr. East has given a more extended description of the regrettable failure. The writer had occasion to discuss the paper by Mr. Knight,[50] and certain statements were made in that connection.

The presence of clay in the bed of the stream indicated that the material should have been removed. It may have been an important factor in the horizontal movement of the up-stream section of the dam. The concrete core-wall acted as others have done. Under the water load it deflected down stream over considerable lengths, the maximum movement at the top, to 1933, being over 7 ft. The thickness of the concrete core-wall was sufficient to have held the water, but there was added a vertical wall of clay, averaging 30 ft thick, an unnecessary feature. The rupture and movement of the up-stream rock-fill were undoubtedly due to the distortion of this clay, aggravated by the rock being squeezed into the clay under its own weight, and to the lubrication of the clay when submerged.

The writer is in agreement with the conclusions expressed by Mr. East except that the fracture of the core-wall could not be attributed to the pressure of the clay wall in front of it. Even if the clay wall had been absent, the movement of the rock mass under water pressure would probably have produced the same result. It is one more example of a failure showing that a core-wall in the center of a dam is a feature to be avoided.

Messrs. Gomez-Perez and Jinich have described in detail the building of five important rock-fill dams in Mexico, the design of which follows, in general, that of California dams. Some comment may be offered on certain features of design.

There seems to be a tendency in the later dams to use a flatter slope on the up-stream side, the reason being that, on the whole, this form is cheaper. The dams were built in layers of relatively small height. There seem to be good reasons why thicker layers would be better, as referred to later. Opinions will differ on this idea, as there are arguments to be presented on both sides. The writer is impressed with the small dimensions of the facing slabs, as experience elsewhere indicates that larger slabs can be used. In general, it would seem that the Mexican engineers have built dams that are adapted to the location, where there is cheap labor and where the importation of expensive machinery was not possible.

---

[50] "The Subsidence of a Rockfill Dam and the Remedial Measures Employed at Eildon Reservoir, Australia," by R. G. Knight, *Journal,* Inst. C. E., March, 1938.

Mr. Reed has presented interesting data regarding San Gabriel Dam No. 2—the causes and results of the partial failure and the destruction and removal of the laminated concrete facing.

Other discussers have contributed important data and information of a general nature that does not call for detailed comment. There are certain other elements referred to in the several discussions, upon which the following observations are made.

A number of those who discussed the paper have disagreed with the writer regarding his statement that no gates of any kind should be placed in the spillway. The conclusion, as expressed, was reached after a study of dams that have been destroyed, either earth or rock-fill. The first principle that must be borne in mind is that safety of the structure must, at all times, be assured as far as it is humanly possible to do so. The danger to life and property that exists on every stream below the dam is the major consideration that should guide an engineer in making the design. It is true, as Mr. Fox states, that rock-fill dams are very stable and will resist some water over the crest without failure. Bear River Dam (Item 10, Table 1) was overtopped in one flood without failure. However, three fairly large dams were destroyed by being overtopped, due to inadequate spillways: Walnut Grove, Lower Otay, and Castlewood Dams (Items 4, 5, and 8, Table 1). It is obvious that a sufficient quantity of water over a rock-fill dam will wash it out, and that in three cases at least, this destruction has occurred.

It will be argued that the gates will be opened in time of flood and thus preserve the dam. There are reasons why the gates may not function at the proper time. The operating force will grow negligent and will fail to draw down the reservoir at the proper time, if at all. Storms and resulting floods are sudden, especially in mountain areas where a warm rain falling on snow will bring down a maximum flood in a few hours. Again, rock-fill dams, as a rule, are built in remote locations and usually only one or two men are in attendance at the dam. The failure of a power line, or the failure or inability of the attendants to operate the assumed gates, may cause the overtopping of the dam.

A further argument is found in the fact that the exceptional flood will bring into the reservoir trees and brush that have accumulated over the years, many of large size. This is a common result of the exceptional flood, noted in many instances. The débris will accumulate against the gate structures, in spite of fender logs. The spillway thus clogged will fail to function and the water will go over the dam. Many years ago the writer was connected with the rebuilding of an earth dam that had been washed out due to clogging of the spillway by débris brought into the reservoir in the flood caused by an exceptional storm. The spillway was formed by openings provided with gates placed between masonry piers. It had functioned for over fifty years without damage but failed in the exceptional storm and flood and the dam was washed out.

In a storage reservoir created by a rock-fill dam there is no need for gates. The dam and the reservoir capacity can be ascertained from a study of stream flow and the requirements of storage. The spillway can be located at the proper elevation and gates to regulate the elevation of water are unnecessary. However, the major factor in reaching a decision is found in the fact that rock-fill dams have been, and can be, destroyed by being overtopped by water. Gates in the spillway have failed to function at times, and since no effort should be spared to make the structure safe in view of the possible loss to life and property, an open spillway of large size, capable of passing all floods with attendant débris, should be provided at all dams. The writer emphatically repeats the statement of the paper that no rock-fill dams should have a spillway dependent upon gates of any kind.

The subject of settlement requires further explanation. The statement of the writer that settlement might be 5% of the vertical height referred to settlement of the loose rock-fill during construction and before the building of the rubble cushion and the impervious face. This was made to emphasize the necessity for deferring the construction of the other two elements of the dam for as long a period as possible after placing the loose rock-fill. If the dam has been properly constructed, the final settlement may be less than 1% of the height, although it will continue to settle for a long period of years. Much depends upon the manner in which the fines have been sluiced into the dam. An extreme case is found in San Gabriel Dam No. 2, where no sluicing was done during construction. During the first heavy storm the dam settled about 12 ft, wrecking the facing. The data of settlement at San Gabriel Dam No. 2, given by Mr. Baumann, seem to refer more to the relation between the quarried rock and the volume within the dam. In general, the settlement discussed herein refers to the settlement during construction and especially after the completion of the dam.

The problem of settlement is one of the most difficult to solve in the construction of rock-fill dams. The higher the dam, the more important becomes the problem. Settlement is intimately connected with the methods used in construction. In some dams, as in Algeria, the engineers have gone to the extreme of making the entire dam of rubble. In others, the loose rock-fill has been deposited in relatively thin layers. There are reasons for so doing, but there seem to be better reasons for the construction of the dam in deep layers. The loose rock, dumped at the top of a fill (say, 100 ft in height), rolls down the slope and by its impact, beds itself among the other rock. It does not merely rest upon a point, because the rock is crushed to a bearing. The fill in such a case is not merely a mass of rock loosely dumped together. The rocks are wedged among each other and form a compact mass, differing greatly from a loose mass. It is quite true that the smaller rock accumulates at, or near, the top of the slope, but the general effect is a compacted mass.

On the other hand, the definition of rubble contains a wide variety of ideas, which are difficult to describe. It is quite possible to build such a wall that will have but little settlement and also to build one that will act in the reverse manner. Merely to place the rock by hand or derrick will not necessarily produce a compact mass. The final results may furnish a means of comparing the loose rock-fill with one of rubble. In Algeria the Ghrib Dam was built entirely of a rubble fill, and a settlement of 0.8% of the height took place, presumably in the first year, while on the contrary, the loose rock-fill at Salt Springs had settled at the crest, only 0.6% of the height in five years. In eleven years the Dix Dam has settled less than 1.0% of its height. The sluicing of the fines into the mass of the dam is an important factor in reducing the total settlement.

The position of the impervious element seems to be agreed on, but some dams have recently been built with the element placed as a vertical wall in the center of the dam. At the Eildon Dam, the top of the vertical core-wall, about 140 ft high, was moved down stream, a distance of about 7 ft as a maximum when the reservoir was filled. At one of the dams in Tunis, with a hollow concrete central wall, about 115 ft high, the crest moved down stream about 2 ft 8 in. on the first filling of the reservoir. The wall was ruptured. The plan of using a central core-wall seems to have arisen from the idea that the weight of the rock-fill is vertical and ignores the effect of water pressure. The actual forces are made up of the rock weighing about 100 lb per cu ft, which acts vertically, and the weight of water at 62.5 lb per cu ft, which acts horizontally. The two forces are of the same order of magnitude and the resultant causes a compression of the material of the dam in a direction that is represented by the resultant of the vertical and horizontal forces. The movement off the core-wall down stream and its possible rupture may be foreseen.

The material of the impervious face was described. In the case of a concrete facing it is believed that a laminated face is unnecessary and will tend to be ruptured. At San Gabriel Dam No. 2 the laminated face was badly ruptured, and it was necessary to install a wooden facing to take its place. It should be recognized that the concrete facing is a very thin element compared to the dimensions of most dams. It is subjected to many forces during settlement which requires that it be of sufficient thickness of integral concrete to withstand distortion. A laminated facing will not perform this function to any great extent. Although much of the discussion has centered around concrete as a material for facing, the writer is of the opinion that timber is an excellent material for the purpose. It will follow the distortion due to unequal settlement and may be renewed, as mentioned by Mr. Huber in his description of the renewal of the facing of Sabrina and Hillside Dams. In this remote location, a timber face is cheaper and is all that is required. The writer also believes that a steel facing has similar good qualities to recommend it. It is permanent and the cost will be a determining factor.

The discussion has centered around some of the higher dams, of which Salt Springs, with a height of 328 ft at the center, is the highest yet built. The higher the dam, the greater the total settlement. The rigid facing, resting as it does on the rock-fill, must move during the settlement. At the bottom and sides of the canyon it must be attached to the rigid cut-off wall. The result is that expansion joints must be installed. Their design is difficult. The comment of Messrs. Steele and Dreyer on the experience at Salt Springs illustrates this point. Although individual situations will always determine the height and selection of the type of dam, it is the belief of the writer that rock-fill dams of a height approximating 200 ft represent about the advisable maximum.

The writer desires to express to those who have discussed the paper his appreciation of their kindness in so doing and for the data given. It is believed that the entire discussion will furnish information of value to those who may have before them the problem of designing dams.

MULTIPLE-STAGE SEWAGE SLUDGE DIGESTION

By A. M. Rawn,[1] M. Am. Soc. C. E., A. Perry Banta,[2] Assoc. M. Am. Soc. C. E., and Richard Pomeroy,[3] Esq.

With Discussion by Messrs. Edward W. Moore, Willem Rudolfs and H. Heukelekian, Hermann Bach, C. E. Keefer, and A. M. Rawn, A. Perry Banta and Richard Pomeroy.

Synopsis

The results of a study of four years' operation of a multiple-stage sludge digestion system are presented in this paper. Satisfactory results have been obtained with a detention period of ten days. The division of the process into stages has afforded an opportunity to obtain data on the component phases of digestion. Part I includes a quantitative study of operating data. This is followed, in Part II, by a report of research on some chemical phases of sludge digestion. Gas, sludge, and sludge-liquor analyses and a discussion of chemical equilibria are included. The presence of traces of unusual compounds in sludge and sludge gas has been verified by micro-analyses.

Introduction

Two batteries of multiple-stage digestion tanks were placed in operation in July, 1931, by the Los Angeles (Calif.) County Sanitation Districts at their Joint Disposal Plant near Harbor City, Calif. The tanks were designed on basic data obtained from experimental work conducted by the Districts and incorporated certain new principles of operation and control. The principal departure from conventional design and operation is the advantage taken of a feature described as gravimetric segregation. Digesting sludge particles will tend to float or to remain in suspension due to adhering or included gas particles. As the digestion of a solid approaches completion, it will sink and remain near the bottom of the mass. Practically all inorganic particles will likewise sink,

---

Note.—Presented at the meeting of the Sanitary Engineering Division, New York, N. Y., January 16 1936, and published in November, 1937, *Proceedings*.

[3] Research Chemist, Los Angeles County Sanitation Dists., Los Angeles, Calif.

thus a combination will be found in the lower strata consisting largely of digested particles and inorganic solids.

In the design of the tanks advantage was taken of this automatic segregation or selection to separate out, and pass ahead, the lower strata to successively lower tanks, at the same time, permitting the upper or active strata to lag and thus to utilize more fully the tank capacity for its intended purpose.

The two batteries of stage digestion tanks are identical in all their principal features. Each battery is rectangular in plan, 56 ft wide and 150 ft long, with an effective depth of about 15 ft. Three transverse walls divide each battery into four rectangular tanks, each 56 ft by 37.5 ft in plan (see Fig. 1). Each battery is built so that the bottom has a slope of 1 on 12. Thus, the sludge surfaces of successive tanks differ by 3 ft. Each tank is equipped with a hopper at its lower end, which is placed directly against the transverse wall dividing it from the next tank in succession. The tanks have concrete covers and each is equipped with two longitudinal baffle-walls extending from within a foot of the bottom, to the cover of the tank, dividing it into three bays of equal capacity.

FIG. 1.—GENERAL LAYOUT OF SLUDGE DIGESTION TANKS

Referring to Fig. 2, man-ways, gas collection, re-circulation and heating lines, sampling and thermometer wells are common to each tank; gas lifts are common to Tanks Nos. 1, 2, and 3; and raw and seed sludge lines go to Tank No. 1 only.

The process of operation is as follows (see Figs. 2 and 3): Primary and activated sludges, plus approximately 20%, by volume, of digested sludge, are introduced into the outer bays of Tank No. 1 in either of the two batteries, and the temperature of the mass is raised to approximately 85° F. To reach the central bay of Tank No. 1, solids must sink to the bottom of the mass in the outer bays and pass under the baffle-walls. To reach the discharge riser pipes, leading from Tank No. 1 to the two outer bays in Tank No. 2, solids must accumulate in the hopper at the lower end of the center bay in Tank No. 1.

FIG. 2.—A TYPICAL SLUDGE DIGESTION TANK

Thus, a process of gravimetric selection is operative in the flow of the sludge, and this selection is repeated in each successive tank until the sludge is discharged into the storage well.

An open pit was constructed adjacent to the digestion tanks which, with a capacity roughly equal to the tanks themselves, serves as a balancing reservoir during poor drying weather, promotes the removal of supernatant liquor, and incidentally adds detention time.

In 1933, the tanks, which had been designed for a detention period of about twenty-five days, were heavily overloaded. Good digestion results were obtained despite a detention period approximating ten days. Beginning in April, 1933, and continuing to date, a detailed study of the performance of the tanks was made. The results of this study over the 4-yr period, May, 1933, to April, 1937, are presented in two sections—the first reporting operation data, and the second, results of research and some of the chemical changes undergone by the sludge during digestion.

OPERATION DATA

Sludge Quantities.—No routine method of sufficient accuracy was available to measure, directly, the volumes and solids contents of the sludges pumped to the digesters. Two indirect methods were used, however, to obtain these quantities.

The first of these two methods makes use of the known volume of sewage flow and the sewage analyses. The primary sludge is calculated from the difference between the analyses of the suspended solids of the influent and settled sewage, and the activated sludge calculation is made from the difference between the non-volatile part of the total solids in the settled sewage and final effluent, together with data on the volatile content of the activated sludge. The second method makes use of digested sludge analyses. An accurate method of measuring the volume of digested sludge, recirculated digested sludge (seed), and supernatant liquor, was developed, and from such data the volume of new sludge pumped to the digesters was computed. Determinations of the ash content of the digested sludge, seed sludge, supernatant liquor, and in the sand and scum accumulations, provide data on the daily input of ash to the digesters. These results, when divided by the average ash content of the solids of the raw sludges, yield values for the input of raw solids.

Calculations of sludge quantities were made by both methods over a 2-yr period ending April 30, 1935. Since that time only the first method has been used. Results of the calculations reduced to quarterly periods are shown in Table 1.

* Corrected for influence of seed from the pit.

The two methods of calculation, when averaged over the 2-yr period, differ by only 1.3%, although individual quarterly periods differ by as much as 11 per cent.

The average solids content of all new sludge pumped to the digesters is 4.7 per cent. Of the new solids added to the digesters, 33% are in the primary sludge and 67% in the activated sludge.

Quarterly averages of the volume of new sludge pumped to the digesters vary from 122 000 gal per day to 160 000 gal per day. The nominal detention time (that is, the design capacity of the tanks divided by the volume of new sludge added per day) varies from 13.5 days to 10.3 days. Actually, the time

Volatile........	62.8	60.7	59.6	58.1	64.1	61.6	60.5	58.2

* After 25 months of continuous operation. † Seven weeks after tanks were cleaned.

of passage of the liquid component of the sludge through the tanks is about 20% less than the nominal detention time, due to the admixture of seed sludge. The time of passage of the solids may be greater or less than this fluid detention time, due to the tendency of the solids either to remain in the upper part of the tanks or to settle to the bottom and thus to pass more quickly through the tank system; it is also increased by the occasional removal of supernatant liquor from the third stage.

Scum Accumulation.—During August, 1933, when the tanks had been in operation for 25 months, composite samples of the sludge were obtained from various elevations of each tank and were analyzed for total and organic solids. A similar survey was made of Battery A between May 11, and May 15, 1934, about seven weeks after all the tanks had been emptied and cleaned.

The percentage of organic matter tends generally to be higher at the higher elevations in the tanks, as shown in Fig. 4. The percentage of volatile matter for the various stages is shown in Fig. 5 and Table 2. The formation of a thick scum layer is well shown in the results of the first test, but seven weeks after the tanks had been entirely emptied there was only a slight tendency toward concentration near the sludge surface in the first tank, with no significant tendency for flotation in the succeeding tanks. The high solids content of the scum layer, together with the observed presence of seasonal seeds at least several months old, as well as quantities of match sticks, hair and bits of rubber, suggest the possibility that, after twenty-five months of operation, the scum layer was largely made up of semi-permanent, indigestible matter, and, as such, would be expected to reduce, greatly, the effective capacity of the tanks. In order to create some idea of the quantity of coarse material, samples of the scum were composited from each battery and washed on an 8-mesh screen, the retained matter being weighed. The results of these determinations are shown in Table 3. It is estimated that the screening from the scum amounted to 12% of the total weight of sludge solids in the tank.

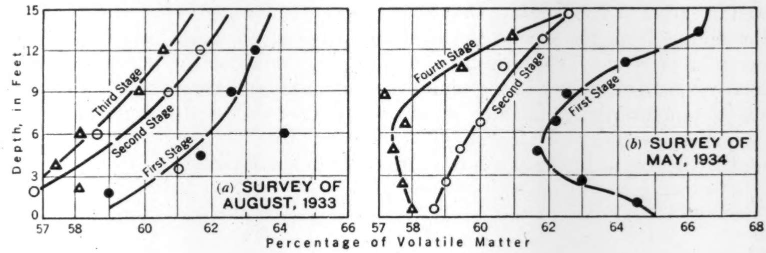

FIG. 5

TABLE 3.—ANALYSES OF SCUM

Description	First stage	Second stage	Third stage
Total solids, percentage of wet weight	16.90	16.04	16.50
Percentage of solids retained on 8-mesh screen	17.9	19.8	21.7
Percentage of organic matter in dry screening	61.8	63.8	67.7

In order to evaluate the effect of the scum accumulation on tank efficiency, experiments were conducted to determine the gas production from samples of the scum. The samples, as taken from the tanks, were placed in gallon bottles and no liquid was added, so that the conditions of tank digestion were simulated as nearly as possible. The results are shown in Table 4.

TABLE 4.—DIGESTION OF SCUM

Stage	Weight, in grams	INITIAL PERCENTAGES:		CUMULATIVE TOTAL GAS PRODUCED, IN CUBIC CENTIMETERS, ON THE FOLLOWING SUCCESSIVE DAYS:							
		Of solids	Of organic matter	1	2	3	4	5	6	7	15
1	1 027	13.97	68.6	5 140	10 420	15 580	20 730	24 020	26 140	27 460	29 760
2	1 034	16.86	62.0	2 720	4 780	6 540	7 970	9 170	....	....	....

For the first four days after removal from the tank, the scum from the first stage produced gas at the rate of 5.0 liters per day per liter of scum. This is well in excess of the averages that have been noted for any of the tanks. Even the sample from the second stage produced gas at an initial rate of 2.6 liters per liter of scum. These results show that, in spite of the accumulation of semi-permanent matter in the scum, there was, nevertheless, enough digestible sludge temporarily retained to make it the seat of very active digestion.

Reduction in Organic Matter and Gas Production.—The percentage of organic matter destroyed in the tanks is obtained from the formula:

$$\text{Fraction digested} = 1 - \frac{W_d}{W_n} \dots\dots\dots\dots\dots\dots (1)$$

in which W_d is the ratio of the weight of organic matter to the weight of ash, for digested sludge; and W_n is the corresponding ratio for new sludge.

The average for the four years ending April, 1937 (see Table 1), shows a reduction in the tanks of 47% of the organic matter added. In weight per day, this equals 17 800 lb.

Computations during the second year of the period covered by this paper showed reduction in the pit of 14% of the organic matter added to the pit; the tank system showed a reduction of 46.3% of the organic matter added, so that the tanks and the pit together effected a 53.8% reduction of the organic matter of sludge which passed through the tanks and the pit. Of the total reduction, 86% occurred in the tanks. The average detention time in the pit was 27 days. The temperature in the pit is lower than that in the tanks.

Gas measurements by stages were made during four separate periods of the first year of the tests. The limited number of meters available prevented the making of simultaneous measurements on all tanks, but single tanks were metered over 10 to 15-day periods. Table 5 gives the totals for both batteries.

In the first three periods the temperature increased in successive tanks. In the fourth period heat was applied only to the first tanks, and the temperature varied but slightly throughout the process. This increasing temperature in the first three periods of measurement probably accounts for the fact that, in two of the periods, the gas production is greater in the third stage than in the second. In the fourth period the gas production is greater in the fourth stage (when full) than in the third, probably because of the greater concentration of solids in the fourth tanks (see Fig. 2) resulting from the removal of supernatant liquor from the third tanks.

TABLE 5.—Gas Production by Stages

Description	Stage 1	Stage 2	Stage 3	Stage 4*	Measured total

Average production, in cubic feet per day	125 300	59 300	50 400	45 000	263 400

* Tanks in Stage 4 were only partly filled; the values in this column were computed as for full tanks, in order to permit comparison with other stages.

In the fourth period of measurement (that is, after the tanks were emptied and cleaned), the gas production in the first tanks was greater than during the other periods, which might seem to indicate an improvement resulting from the removal of the floating accumulation. This effect, however, may be accounted for adequately by two other factors, the first being the reduction of effective capacity by 13%, due to sand accumulation before cleaning, and the other being the higher temperature after cleaning.

The gas metered is slightly less than the actual production, since there is some tank leakage. On the basis of tests made when the tanks were new, the leakage under conditions of metering would be expected to be about 7 000 cu ft per day, which, added to the average daily production shown in Table 5, indicates an average daily total of 270 000 cu ft.

The gas production was measured at an average pressure of 765 mm of mercury and at 25° C. The average density of the gas under these conditions was determined experimentally to be 1.047 grams per liter. Hence, the weight of gas actually recovered was 17 400 lb per day. The average weight of organic matter destroyed over this period was 16 300 lb. Thus, the weight of gas produced was 107% of the quantity described as "weight of organic matter destroyed." This value (107%) takes no account of carbon dioxide (CO_2), ammonia (NH_3), and volatile acids lost from samples of new or digested sludge upon drying during analysis. If these losses were taken into account a still higher value would result.

In order to determine what additional gas production might be expected from longer detention times, samples of sludge from the fourth tanks were placed in bottles in the laboratory and the subsequent gas production was measured. These tests were continued until the rate of gas production had dropped to roughly one-tenth of the initial rate for the samples from the fourth tanks, or to about 2% of the rate in the first digestion tanks. In the digestion tanks the sludge yielded an average of 343 cu cm of gas per gram of solids added, or 485 cu cm per gram of organic matter added. Table 6 gives the gas yields on the same basis for the additional periods of detention.

TABLE 6.—Gas Production After Sludge Leaves Tanks

Stage	Date started	Detention, in days	Average temperature, in degrees Fahrenheit	Gas Produced			
				In Cubic Centimeters per Gram of Original:		Total produced, plus subsequent digestion, in cubic centimeters per gram of organic matter added	Percentage of gas produced in tanks
				Solids	Organic matter		
	(1)	(2)	(3)	(4)	(5)	(6)	(7)
1	August 14......	20	80.5	64	91	576	84
2	August 15......	19	80.5	60	85	570	85
3	November 1....	23	86.0	80	113	598	81
4	November 2....	22	86.0	77	108	593	82

Detailed results of the analyses of the gas will be given subsequently. The average carbon dioxide content is about 32%, the remainder being nearly pure methane gas. The content of hydrogen sulfide, H_2S, rarely exceeds 0.02 per cent. About 50 000 cu ft per day is burned in a water-heating boiler used to heat the digestion tanks. After the boiler had been in service for about eight months, it was observed that corrosion of the flues was taking place, leading to the deposition of plugs of ferrous sulfate in the lower ends of the flues. Use of a forced draft eliminated the difficulty by preventing condensation of moisture in the flues.

A 200-hp gas engine, which was installed in May, 1935, uses about 110 000 cu ft per day of the gas. The engine has run 99.3% of the time since installation, and has generated an average of 182 hp. The cost of producing this power, in terms of equivalent electrical units, is 0.18 cts per kw-hr. This includes 10-yr amortization at 6% interest, and all operation and maintenance costs. The cylinders show no corrosion attributable to the gas. Valves are ground two or three times each year; rings were changed at the end of 23 months.

The piping of the gas-collecting system has shown no deterioration. The concrete and metal work in the digestion tanks was found to be in good condition except that in the fourth tanks the concrete above the sludge line shows moderate surface deterioration. In these tanks some air occasionally becomes mixed with the gas, and probably oxidizes hydrogen sulfide to sulfuric acid. In a few places the gas that diffused out through small cracks in the concrete has caused detectable deterioration on the exterior of the tanks where the concrete is exposed to the air. The concrete of the tops of the tanks, which are covered with a coat of tar and 12 in. of soil, is apparently unaffected, but electrical conduits laid in the soil have been practically destroyed in some places. Free sulfur has been deposited on the surface of the soil in a few small areas. It is surprising to observe these effects from such a small percentage of hydrogen sulfide in the gas.

Heating System.—The tanks are heated by means of 2-in., extra heavy, wrought-iron coils arranged vertically along the partition walls of one side of each of the first three tank compartments. Individual runs of pipe of each coil were placed in a vertical position to prevent the settlement of solids on the pipe. The coils of the first tanks were designed to supply enough heat to raise the temperature of the new sludge to the operating temperature (85° F). In the succeeding tanks only enough coil area was provided to compensate for estimated heat loss by radiation.

Soundings taken with a thermocouple indicate that there is no temperature stratification and that the tanks are quite uniform in temperature throughout the depth of each unit (see Table 7). When the tanks were emptied and cleaned after thirty months of service, approximately 0.5 in. of limey scale was removed from the heating coils. Prior to the cleaning it was necessary to use all the coils in the first three tanks or stages in order to raise the temperature to 85° F, but subsequent to the cleaning, hot water has been circulated only through the coils of the first tanks. Some minor difficulty has been experienced with air becoming trapped in the bends in the coil system. The tanks are handling more than twice the designed capacity, and additional heating surface would be desirable in the first tanks.

* Bottom of tank.

A study of the sludge-heating data shows that 675 ft of 2-in., extra heavy, wrought-iron pipe in the first tanks transmitted heat at the rate of 84 Btu per day per ft of pipe per degree of temperature differential. This value was obtained after thirty months of service when the coils were covered with lime scale. After the scale was removed and the condition of the pipes was equivalent to new, the conductance rate was 347 Btu.

From May 15, to June 11, 1934, observations were made on the quantity of heat supplied to the digestion system. The heat transmitted daily to the tanks was 13 900 000 Btu as calculated from the sludge-heating water. New sludge at the rate of 129 000 gal per day, and at 73.2° F, was pumped to the digesters. It is calculated that 13 400 000 Btu per day was required to raise this quantity to the temperature of the first tanks. The difference of 500 000 Btu per day between the heat supplied and the heat appearing in the sludge is due: (*a*) To experimental error; (*b*) to radiation from the tanks; and (*c*) perhaps to endothermic requirements of the digestion process; or (*d*) to a combination of Causes (*a*), (*b*), and (*c*).

The difference between the free heat content of the sludge added to, and leaving, the digesters was 12 700 000 Btu per day. The heat added to the sludge was 13 900 000 Btu per day; there was left 1 200 000 Btu, to account for radiation and endothermic requirements of the entire process. C. E. Keefer, M. Am. Soc. C. E., and Herman Kratz [4] found through laboratory experiments that the digestion process in general is endothermic, their experiments showing a net heat absorption varying from 154 to 433 calories per gram of organic matter destroyed. The total destruction of organic matter in the digestion tanks of the Districts, over the corresponding period, averaged 13 300 lb, or 6 030 kg per day. Using the minimum value cited by Messrs. Keefer and Kratz, this destruction should require 929 000 kg-cal, or 3 690 000 Btu, a quantity of heat three times as great as that which appears to be available (1 200 000 Btu).

A similar conclusion may be reached by comparing the temperatures in the second and fourth stages during the period when no heat was being applied beyond the first stage. On the basis of the minimum values given by Messrs. Keefer and Kratz for the endothermic requirements in the latter stages of digestion, it is calculated that the sludge temperature should fall 2.3° F even with no loss by radiation. Actually, the cooling, including that due to heat loss by radiation, was less than 0.5° F.

Foaming.—Foaming is occasionally observed in the first and second tanks. Gas space of 6 ft in the first tanks and 4 ft in the other tanks is provided to accommodate the foam, and for four years after the tanks were placed in service no trouble was encountered. In January, 1936, the foaming became serious, rising to the tops of the tanks and filling the gas lines. Seed sludge was being taken at that time from the fourth tanks. It is believed that this sludge was not far enough advanced in digestion to serve as satisfactory seed, an indication of this being the fact that the content of volatile acids was 600 ppm to 850 ppm (as acetic acid). Seed was then taken from the pit, whereupon the foaming subsided. However, the difficulty has occasionally recurred since that time although the seed is now regularly taken from the pit. It is now believed that the trouble lies in the failure to secure adequate mixing of the seed with the new sludge. It has not been convenient to pump seed to the tanks more than once each day. Between pumpings of seed, one of the first tanks may receive a volume of new sludge nearly as great as the volume of the tank. The pumping of a quantity of seed into the outside bays may not permit proper seeding of the entire mass. When the foam rises to a danger point, some of the raw sludge is by-passed to subsequent tanks until the foam subsides. This procedure has effectively prevented operating difficulty.

---

[4] "The Interchange of Heat During Sludge Digestion," by Messrs. C. E. Keefer and Herman Kratz, *Sewage Works Journal*, Vol. 5 (1933), p. 3.

Stirring.—The tanks were equipped with gas lifts for the purpose of stirring the sludge, but a comparison of the performance of one battery operated with the gas lifts as against the other battery operated without stirring, failed to indicate any difference. With the degree of mixing made possible by the tank arrangement it is doubtful whether any additional stirring is warranted.

Sludge Drying.—The sludge drying beds comprised 2.34 acres of underdrained sand beds, 6.0 acres of diked field, and 2.9 acres of shallow lagoons. The diked fields are constructed by grading open fields so that the sludge depth is about 2 ft. The soil is a tight adobe that leaves little chance for seepage or under-drainage. Data indicate that sludge was dried at the rate of 663 tons per acre per yr on the sand beds and at the rate of 342 tons per acre per yr on the "field." About 25% of it was wasted directly from the digestion tanks to the drying beds. For convenience in operation the other 75% was pumped to the pit before passing to the beds or field. No difference in drying characteristics has been noted in the two sludges. Both types become dry without odor nuisance or the breeding of house flies.

Measurements of the rates of draining of sludge pumped to the sand beds gave rather erratic results, indicating considerable variation in the drainability of sludge from time to time. The most that can be concluded, from the twenty beds measured, is that, in general, when the sludge from this installation is pumped to the beds with a solids content of $4\frac{1}{2}\%$, it will lose about one-half its moisture by drainage in the first 48 hr. The remainder of the moisture is lost by evaporation.

* Does not include cost of land. † Does not include cost of removing sludge from beds. ‡ 8% of Column (2). § Column (6) ÷ Column (7). || Column (6) ÷ Column (8).

Costs.—Table 8 was prepared to illustrate costs for digestion and for drying on underdrained beds and open fields or lagoons. Since approximately 75%

of all the digested sludge is transferred to the pit prior to drying, the cost of the pit is included with the tank costs. It has little influence on unit costs for digestion. The cost of land on which tanks, pit, and drying areas are laid out is not included. Sludge is delivered wet, on the beds, to a fertilizer contractor who assumes the cost of its removal. The contractor pays the District $2 per ton of dry solids delivered on the beds and lagoons.

The gas engine, operated on gas from the digesters, has effected a net saving in power costs of $480 per month. No credits for this have been applied to the costs in Table 8.

Chemical Studies

Multi-stage digestion as applied in this installation affords an excellent opportunity to study, under plant-scale operation, the chemical changes occurring in the digestion process. Although some of the information presented is abstract, its inclusion is thought to be of value in helping to furnish a clearer concept of the fundamental nature of the digestion process. Basic information obtained through studies of this kind may be expected to point the way to the solution of some of the problems of sludge digestion. The following phenomena were given attention in a chemical study carried on principally during the year, May, 1933, to April 1934: Changes occurring in the sludge liquor, changes of the ether-soluble matter, nitrogen balance, and composition of the gas.

Changes in the Sludge Liquor.—Analyses were made on samples of clear liquor separated from the sludge leaving each stage of the digestion process. No complete analyses were made on liquor from the pit; but instead, two samples of sludge from the fourth tanks were retained in bottles at 86° F for an additional period of 23 days and analyzed at the end of that time. These latter samples represent approximately the results that might be expected from a total digestion time of 32 days.

Most of the analyses were made on samples taken during two test periods: August 11 to 22, 1933, and most of the month of October, 1933. No essential differences appeared between the results covering the two periods, except in the case of phosphate. Table 9 shows the average results of all valid analyses, except that the phosphate values for the two test periods are tabulated separately.

The "mixture" is computed from the known proportions by volume of new and seed sludges added to the first stage. Analyses of filtered sewage are taken as representative of the liquor accompanying the new sludge. Actually, the composition of the liquor begins to change as soon as the sludge settles from the sewage. The method of calculation has the effect of including in the change attributed to the first stage that which occurs in the sludge in the bottom of the settling tanks.

Bicarbonate values in Table 9 were computed from the ion balance, as bicarbonate titrations were not made at the time of these liquor analyses. Some subsequent work on the bicarbonate titration indicates that, in liquor from digested sludge, the computed value is less than the experimental value by an average of about 290 ppm as HCO_3. The pH-values are derived from the computed bicarbonate concentrations, the carbon dioxide content of the gas,

[5] "Hydrogen Ion Concentration and Bicarbonate Equilibrium in Digesting Sludge," by A. P. Banta, Assoc. M. Am. Soc. C. E., and Richard Pomeroy, *Sewage Works Journal*, Vol. VI, 1934, p. 234.

Further consideration of some of the constituents reveals a number of interesting relationships, discussed in the following paragraphs.

Sulfate.—The rapid reduction of sulfate in the first stage is undoubtedly caused by bacterial de-oxidation with attendant liberation of sulfide ion. However, there is practically no sulfide in solution, the sulfur going to form ferrous sulfide. The apparent increase in sulfate in the later stages may have been due to chance variation of samples.

Phosphate.—Table 9 shows that in August the phosphate concentration increased regularly through the digestion tanks whereas in October the phosphate was at a maximum in the first tank and decreased progressively thereafter. It was thought that the decrease in the second period might be explained by precipitation of magnesium ammonium phosphate. This seemed likely in view of another observation. A flume that carries supernatant liquor from the pit has accumulated a crust of crystalline material, in some places to a thickness of an inch. Analyses of two samples of this material showed it to be about 96% $Mg\,NH_4\,PO_4 \cdot 6\,H_2O$.

In order to determine if this compound may precipitate in the digestion tanks, two solubility tests were made by saturating liquor from digested sludge with the pure compound, keeping the solution in equilibrium with sludge gas of known carbon dioxide content. The results yielded solubility products of of 1.06×10^{-12} at 25° C and 1.33×10^{-12} at 30° C.

On the basis of these results it is calculated that the digested liquor from the tanks, having the hydrogen-ion concentration and the content of magnesium and ammonium shown in Table 9, would be able to hold 305 ppm of phosphate in solution before becoming supersaturated. After 32 days of detention the liquor could hold 157 ppm. Hence, it does not seem possible that magnesium ammonium phosphate could precipitate in the digestion tanks, and the peculiar behavior of the phosphate in the October series of tests remains unexplained. The deposition in the flume can be explained as due to the loss of carbon dioxide and the resultant rise in pH. Such loss of carbon dioxide would be expected because of turbulence in the flume in question. If this loss allows the pH-value of the pit liquor to rise to 8.0, the proportion of phosphate that can be held is reduced to about 18 ppm (at 25° C); any excess over this concentration should precipitate.

Volatile Organic Acids.—The increase of organic acids in the first stage and their subsequent destruction supports the observations of other investigators. An attempt was made to analyze completely the volatile organic acids of sludge liquor from the first tank. A satisfactory conclusion was not reached, but by modification of an ether-extraction procedure,[6] tentative results were obtained, as follows:

Acid	Percentage
Formic	0
Acetic	63
Propionic	33
Butyric	0.1
Valeric	4

---

[6] "Determination of Formic, Acetic, and Propionic Acids in a Mixture," by O. L. Osborn, H. G. Wood and C. H. Werkman, *Journal of Industrial Engineering Chemistry*, Vol. 25, 1933, p. 247.

A part of the fraction reported as valeric acid may be caproic acid. The large percentage of acetic acid undoubtedly came from decomposition of carbohydrates, whereas the presence of valeric acid suggested the de-aminization of amino acids formed by the bacterial hydrolysis of proteins. Tests for acids of the phenol group showed about 0.7 ppm (as phenol) in the liquor from the first stage, with smaller quantities in subsequent tanks.

Calcium.—The possible saturation of the sludge liquor with calcium carbonate is of some interest. In a solution saturated with calcium carbonate and in equilibrium with a gas phase containing carbon dioxide at a partial pressure, $p\,\mathrm{CO_2}$, the following relationship should hold:

$$\frac{(\mathrm{Ca}^{++})\,(\mathrm{H\,CO_3})^2}{p\,\mathrm{CO_2}} = K \ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

The value of K is dependent upon the ionic strength of the solution according to the equation:

$$\log K = \log K_0 + 2\,\sqrt{\mu} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

in which μ is the ionic strength and K_0 is the value of K at zero ionic strength. The values of K corresponding to the ionic strengths of the various sludge liquors have been derived from published data.[7] Results of calculations of the concentrations of calcium necessary to saturate the various sludge liquors are shown in Table 10. In all cases the calcium found is greater than the proportion calculated to be necessary to saturate the solution. The excess is probably accounted for as supersaturation of the liquor with respect to calcium carbonate. That the liquor is supersaturated is supported by observations made when the tanks were opened for cleaning. It was found that the walls, even in the first stage, were partly covered with a hard thin deposit of lime.

TABLE 10.—SOLUBILITY OF CALCIUM CARBONATE, $\mathrm{Ca\,CO_3}$, IN SLUDGE LIQUOR

Liquor	Ionic strength	Values of K (concentrations, in mols per liter)	Values of partial pressures, $p\,\mathrm{CO_2}$, in atmospheres	Bicarbonate, $\mathrm{HC\,O_3}$ in parts per million	Ca required to saturate solution in parts per million calculated	Ca, in parts per million, observed
First tank........	0.062	4.4×10^{-6}	0.345	2 124	50	190
Second tank......	0.079	5.1×10^{-6}	0.313	3 059	25	251
Third tank.......	0.088	5.6×10^{-6}	0.303	3 929	16	277
Fourth tank......	0.094	5.9×10^{-6}	0.292	4 502	13	282
Digested 32 days..	0.113	6.6×10^{-6}	0.29	5 867	8	290

It is surprising that sufficient precipitation does not occur to cause a decline of calcium concentration before the sludge leaves the tanks, but there is evidence that such a decline does occur in the later stages of prolonged digestion. This evidence appeared in the samples which were subjected to the 23 days of additional digestion. A composite of the liquor from these two samples taken at the beginning of the experiment showed 332 ppm of calcium. At the end, the two samples showed, respectively, 316 and 263 ppm. Table 9 does not show any decrease for the reason that chance variations of individual samples obscure an effect which might be revealed by averages of greater numbers of samples.

---

[7] *Journal*, Am. Chemical Soc., Vol. 51, p. 2082 (1929).

Iron.—The solubility of ferrous carbonate in sludge liquor is governed by equilibrium expressions similar to those applying to calcium carbonate. On the basis of solubility data,[8] it is calculated that if the sludge liquor from the fourth stage contained 0.02 ppm of iron as ferrous ion, the solution would be saturated with ferrous carbonate. The fact that much larger concentrations prevail suggests that the iron may be in the form of un-ionized or colloidal compounds. Supersaturation with respect to ferrous carbonate may also be a factor.

In one instance when a very large percentage of ferrous iron was present in the sludge going to the digestion tanks, the green color of the iron compounds persisted throughout the digestion process. A sample of this green sludge, when treated with acid, liberated a quantity of carbon dioxide that could be accounted for only by assuming that the iron was present as ferrous carbonate.

Digestion of Ether Soluble Matter.—Determinations of ether soluble matter were made on samples of primary, activated, tank, and pit sludges. (An ether-soluble determination is made as follows: A weighed sample of dried (105° C), pulverized sludge is placed in a weighed Gooch filter; washed with hydrochloric acid (H Cl), and water; dried and re-weighed; extracted for 3 hr with ether under a reflux condenser; dried and re-weighed, the loss in weight being reported as a percentage of ether soluble material on the basis of the original dry weight. By this procedure the insoluble soaps are represented by free fatty acids in the ether extract.) All analyses but one were made on samples taken between May 15 and June 10, 1933. The results are shown in Table 11.

TABLE 11.—PERCENTAGE OF ETHER SOLUBLE MATTER IN SLUDGES

Type of sludge	Number of analyses	Maximum	Minimum	Average	Type of sludge	Number of analyses	Maximum	Minimum	Average
Primary.....	6	20.7	16.0	18.2	Digested....	7	11.6	7.8	9.1
Activated....	6	22.7	13.9	20.3	Pit seed.....	2	8.5	6.7	7.6

Composites of the material separated by ether extraction were analyzed for various constituents. In the case of the ether soluble material taken from the digested sludge, the free acids, after being separated from the remainder and dried, changed in part to a material that could be re-dissolved neither in fat solvents nor in dilute alkali. The change probably involved oxidation and polymerization. A repetition of the extraction and drying of the part that was soluble in potassium hydroxide caused more of it to become insoluble, so that it is estimated that at least one-half the free acids in the ether soluble material of the digested sludge were of an unstable type; the true fatty acids may be only a small proportion of the total acid fraction. In view of this behavior, it seems likely that the original digested sludge contains substances which, in the original state, would be soluble in ether, but which change to insoluble forms when the sludge is dried, acid treated, and re-dried during analysis.

---

[8] *Journal*, Am. Chemical Soc., Vol. 40, p. 879.

Table 12(*a*) shows the results of the analyses. Some of the acid fraction may have been phenolic acids. A qualitative test for phenolic acids in the ether extract from the digested sludge gave a strong positive result; and yet, as noted previously, only traces of phenols are present in the liquor.

TABLE 12.—Ether-Soluble Matter

Equivalent weight of acids	306	309	272	....	....	..

* Insoluble soaps in sludge.

Each 100 lb of ether soluble material entering the digestion tanks contains the quantities of various constituents shown in Table 12(*b*); the fates of these constituents are also shown. The "fatty acids" are present in the sludge in combination with calcium and magnesium as insoluble soaps. Taking into account the foregoing observations, indicating that very little true fatty acids are present in the digested sludge, it appears that the insoluble soaps are destroyed quite completely in the digestion process. The very low reduction of the non-saponifiable matter (mineral oils, etc.) is to be expected.

Calculations based upon the equivalent weights of the fatty acids and the other data as given, indicate that the quantities of acids destroyed per day is equivalent to 316 lb of calcium. An equivalent quantity of bases should be released. From the liquor analyses it is calculated that 208 lb of calcium and 33 lb of magnesium per day appear in the sludge liquor. If the magnesium is converted to the calcium equivalent and added to the value for calcium, the result is 263 lb of calcium equivalent. The agreement of this result with 316 lb from the grease analyses, is considered good in view of the many sources of error. The difference is in the direction that would be accounted for by the loss of some of the acids in the digested-sludge analysis through oxidation and polymerization, and by the precipitation of calcium carbonate in the tanks.

It was thought that phosphorous-containing fats might be a significant source of the phosphate that appears in the sludge liquor. However, calculations indicate that only 7 lb per day of phosphate would be released by the digestion of the ether soluble matter, whereas the sludge liquor analyses of August, 1933, showed 70 lb per day going into solution.

Nitrogen Balance.—Nitrogen analyses were made on samples of wet sludges during May, and June, 1933, with results as shown in Table 13(*a*). On the basis of estimates of the weights and volumes of the various sludges pumped during May and June, 1933, calculations have been made of the "through-put" of nitrogen, with results as shown in Table 13(*b*). The quantities of nitrogen entering and leaving the tanks are in good agreement, indicating that there is no appreciable loss. Since this is a rather important point, a careful experiment was performed to determine if any loss of nitrogen could be detected. A laboratory sample of a mixture of strained raw and activated sludges was seeded, and carefully sampled; and five total nitrogen determinations were made by the Kjeldahl method. The mixture was incubated for 33 days, sampled, and analyzed as before. The nitrogen balance in digestion, in parts per million of nitrogen, was found to be as follows:

TABLE 13.—NITROGEN BALANCE

Probable error of difference	10	

The average concentration of nitrogen after incubation is 28 ppm greater than in the original mixture. When a correction is made for the decrease in weight of the sludge due to loss of gas, the quantity of nitrogen in the final mixture, on the basis of the original weight, is less than in the original mixture by 7 ppm, or 0.34 per cent. On the basis of deviations of the individual determinations it is estimated that the probable error of the difference is 10 ppm; hence, the apparent loss is not significant. It is probable that if an actual loss did occur, it did not exceed 17 ppm of Kjeldahl nitrogen. These results are in accord with conclusions of Messrs. A. M. Buswell and C. S. Boruff.[9]

As the sludge originally separates from the sewage, 98.6% of the nitrogen in it is held in the solids, and 1.4% is in the form of ammonium compounds or organic nitrogen in solution. When the sludge leaves the tanks, 56.8% of the original nitrogen is still held in the solids, and 43.2% is in solution. At the end of 23 days of additional digestion, the original nitrogen still held in the solids is reduced to 41.3 per cent.

If the sludge from the tanks is dried on sand beds, two-thirds of the water originally present with the sludge will have been removed as supernatant liquor and as drainage from the beds by the time the water ceases draining from the sludge. The water remaining with the sludge will hold 14.2% of the nitrogen originally present in the sludge. Prolonged and thorough drying of the sludge removes the ammonium nitrogen almost completely, but when the sludge is dried, as is usual, to about 50% moisture, 15% of this ammonium nitrogen, and presumably all the soluble organic nitrogen, remain in the moisture of the sludge. Of the nitrogen originally present 60% will still be available for fertilizer value. If the sludge is digested for an additional 23 days and then dried to 50% moisture, 46% of the original nitrogen will still be available. Of the nitrogen fertilizer value remaining after digestion in the tanks, 23% is lost due to digestion in the pit. These considerations point to the desirability of a short digestion period when the sludge is to be used for fertilizer. It must be noted, however, that a substantial amount of digestion occurs in the sludge from the tanks during drying; this is not taken into account in the foregoing calculations.

The digestion of nitrogenous matter roughly parallels the digestion of other organic matter, with the result that the percentage of nitrogen in the solid organic matter does not show any great change. If the insoluble nitrogen is calculated as percentage of the solid organic matter, the value is 5.79% for the new sludge, 6.51% for the sludge from the tanks, and 6.09% for the sludge after 32 days of digestion. The total nitrogen in the sludge from the pit (including the soluble portion) dried on the sand beds, as calculated from the analyses of the new sludges and the analyses of the sludge liquors, should be 6.54 per cent. Samples of dried pit sludge taken in May, 1934, showed a nitrogen content corresponding to 6.49% of the organic matter (average of eight analyses from two beds). Thus, again, all the nitrogen is accounted for. The average organic content of this sludge, lowered in part by inclusion of sand, was 47.5%; hence the nitrogen was 3.08% of the dry weight of the sludge. Nitrogen analyses at other times indicate that this represents average conditions.

---

[9] "The Relation Between Chemical Composition of Organic Matter and the Quality and Quantity of Gas Produced During Sludge Digestion," by Buswell and Boruff, *Sewage Works Journal*, Vol. IV, 1932, p. 450.

Summary of Changes in the Solids.—If the proteins of the sludge solids are assumed to be 6.25 times the nitrogen percentage, the organic matter may be divided into ether soluble matter, protein, and cellulose and miscellaneous, and the fates of these three types of organic matter may be calculated. Results of such calculations, on the basis of 100 lb of original organic matter, are shown in Table 14.

TABLE 14.—ANALYSIS AND FATE OF ORGANIC MATTER IN SLUDGE

Gas Analyses.—Samples of gas from various stages of the digestion process and from the laboratory supply, a mixture from all the tanks, were analyzed for various constituents. The results, subject to certain limitations, as described subsequently, are shown in Table 15.

Carbon Dioxide.—Several analyses for carbon dioxide were made by the usual absorption method. In other cases, the density of the gas was determined and the carbon dioxide percentage was estimated from an experimentally determined correlation between density and percentage of carbon dioxide.

From the known solubility of carbon dioxide in water, it is calculated that the sludge liquor from the last tanks contains 373 ppm of free CO_2 in solution. When sludge is dried for analysis, a large additional quantity of this gas is lost by decomposition of the bicarbonates, especially ammonium bicarbonate. This loss would amount to an average of 3 030 ppm for all the liquor from the tanks. In volume, the free carbon dioxide and the bicarbonate, CO_2, that would be lost upon evaporation would amount to 30 100 cu ft per day, a quantity one-third as great as that of carbon dioxide in the gas evolved from the tanks.

Hydrogen Sulfide.—Various methods were tried for the H_2S-determination. Precipitation of lead sulfide, Pb S, from a lead acetate solution containing 2% acetic acid, with filtration and weighing of the precipitate, gave fairly consistent results; but this method is open to theoretical objections. Results considered to be more reliable were obtained by passing the gas through bromine water, and precipitating and weighing the resulting sulfate as barium sulfate.

In the discussion of iron in the sludge liquor, evidence was given showing the presence of ferrous carbonate in the sludge on at least one occasion. The iron content of the sewage at this plant is usually high due to trade wastes. The sludge contains an average of 2.46% of iron (as Fe). The efficiency with which the sulfide, formed by reduction of sulfate and decomposition of organic

matter, is converted to ferrous sulfide, indicates that the iron is in the form of a quite reactive compound. It seems quite probable that the sludge usually contains ferrous carbonate.

Equilibrium considerations lead to some interesting conclusions regarding the percentage of hydrogen sulfide in the gas from a sludge containing both ferrous carbonate, $Fe\,CO_3$, and ferrous sulfide, Fe S. The following equilibrium may be considered to exist:

$$Fe\,S + CO_2 + H_2O = H_2S + Fe\,CO_3 \quad \ldots\ldots\ldots\ldots\ldots (4)$$

The equilibrium constant expression is:

$$\frac{p\,H_2S}{p\,CO_2} = K \quad \ldots\ldots\ldots\ldots\ldots (5)$$

From data on the solubilities of ferrous carbonate [9] and of ferrous sulfide,[10] the value of K is computed to be 10^{-4}. This may be in error by as much as a factor of two due to uncertainty in the solubility of ferrous sulfide.

If the gas and sludge liquor were really in equilibrium with both ferrous sulfide and ferrous carbonate, and if the gas contains about 30% of carbon dioxide, the concentration of hydrogen sulfide should be about 0.003 per cent. Higher values might be expected if there is insufficient opportunity for reaction of the sulfides to gain equilibrium with the $Fe\,CO_3$. Low values might be found if a trace of air should get into the digestion tanks, because conditions would be favorable for a rapid oxidation of the hydrogen sulfide.

Referring to Table 15(*b*), it is seen that one sample of laboratory gas gave a value seventeen times as great as the computed value, and that, in other cases, the hydrogen sulfide was less than one-thirtieth of the computed value. Fortuitously, the average concentration of hydrogen sulfide is in fair agreement with the value of 0.003 per cent. The most that can be concluded is that, under the conditions of these observations, the equilibrium serves as a moderating factor, holding the percentage of hydrogen sulfide within limits.

According to theory, the concentration of hydrogen sulfide should be independent of the hydrogen-ion concentration as long as both iron compounds are present. Hence, it should be the same at all stages of digestion, except for small changes in the percentage of carbon dioxide. The data show no pronounced trend in the percentages of hydrogen sulfide by stages.

Analyses for mineral sulfides in the sludge show an increase of 153 lb per day in the digestion process. If all this sulfur formed hydrogen sulfide instead of being combined with iron, it would be equivalent to 0.7% of the gas. However, even if no iron were present, approximately one-half this hydrogen sulfide would remain in solution in the sludge liquor.

From the known solubility of hydrogen sulfide in water, it is calculated that sludge liquor in equilibrium with gas containing the average concentration of hydrogen sulfide (0.0043%) would contain about 0.13 ppm of free hydrogen sulfide. The total dissolved sulfides, calculated from the pH-value and the ionization constant [11] of hydrogen sulfide, should be about 0.3 ppm. The gas which, in one case, was found to contain 0.058% of hydrogen sulfide must have come from liquor containing about 4 ppm of sulfides.

[11] "Relationship Between Free Hydrogen Sulfide and Total Sulfides in Sewage," by Richard Pomeroy, *California Sewage Works Journal*, Vol. VI, No. 2 (1934), p. 54.

Carbon Monoxide, Hydrogen, and Phosphine.—Carbon monoxide was determined by the iodine pentoxide method, and hydrogen by combustion with palladium catalyst and weighing of the water. These methods do not positively establish the presence of either gas; they do establish upper limits for the concentrations. Phosphine was determined by oxidation with bromine water and subsequent determination of the phosphoric acid. The presence of phosphine in sludge gas has been suggested by other writers, but apparently has not previously been determined. The quantity is a mere trace.

Ammonia.—From the ionization constant of ammonium hydroxide, the concentration of ammonium ion in the liquor, and the pH-value, it is possible to compute the concentration of ammonium hydroxide, NH_4OH, in the liquor. From the known solubility of ammonia one may compute the equilibrium percentage of NH_3 in the gas. Table 16 shows the calculated NH_3 content of the gas in equilibrium with the various liquors which were analyzed.

TABLE 16.—COMPUTED VALUES OF AMMONIUM CONTENT

Liquor discharge	Ammonium nitrogen, in parts per million of nitrogen	Hydrogen ion concentration, pH	Ammonium hydroxide, NH_4OH, in parts per million of nitrogen	Percentage of ammonia, NH_3, in the gas
First tank	444	6.74	1.33	0.00016
Second tank	583	6.93	2.74	0.00033
Third tank	692	7.06	4.43	0.00053
Fourth tank	757	7.14	5.90	0.00071
Twenty-three days additional digestion	1 026	7.26	10.26	0.00123

The analyses of sludge liquors were made in all cases on the liquor flowing from one tank to the next. Hence, they do not represent the average composition of the liquors in the tanks. The gas from any tank would be expected to be intermediate in composition between the gases in equilibrium with the liquors entering and leaving that tank. It is upon this basis that values shown in Table 15 were estimated.

Ammonia in gas from the fourth stage was determined by bubbling a large volume through acid solutions and subsequently adding potassium hydroxide, KOH, and distilling and titrating. Two determinations gave 0.00088% and 0.00093% as against the computed value of 0.00062 per cent.

Olefines.—A volume of 1 800 liters of gas from the first stage was passed at a rate of about 20 liters per hr through bromine water and then into a 2-liter flask cooled with ice. At the end, the excess bromine was allowed to evaporate and the reaction tube and receiving flask were washed with ether. Evaporation of the ether solution left 2 or 3 grams of strongly lachrymatory solid and liquid bromine compounds.

If the gas contained ethylene, ethylene dibromide should be present in the product. An attempt was made to remove ethylene dibromide by vacuum distillation, but none could be obtained. If it was present, it certainly did not exceed 0.01%, and probably was not more than 0.001 per cent. From the solid portion of the mixture a small quantity of a compound was crystallized, which was identified as 1, 2, 3, 4 tetrabromo-butane, showing the presence of buta-diene ($CH_2 : CH \cdot CH : CH_2$) in the gas. However, the proportion of this olefine in the gas did not exceed 0.1% and possibly was not more than 0.001 per cent.

Other Hydrocarbons.—A sample of gas was analyzed by the research laboratory of a local oil company to determine the possible presence of hydrocarbons other than methane. Results were reported as follows:

Ethane, C_2H_6	0.04%
Propane, C_3H_8, and butane, C_4H_{10}	0.01%
Pentane, C_5H_{12}, and heavier	0.07%

Nitrogen.—The usual method of combustion in a combustion pipette is not satisfactory for determining quantities of nitrogen of the order of 2%, or less. No apparatus was available for more suitable methods.

Facts previously cited lead to the belief that very little nitrogen is present in the gas. Analyses of sludges to and from the digestion system did not indicate any loss of nitrogen from the sludge. Laboratory experiments indicated that the loss, if any, probably did not exceed 17 ppm. If this loss went to elemental nitrogen, it would amount to 0.12% by volume of the gas. Atmospheric nitrogen dissolved in the sewage (not included in the nitrogen analyses) would be gassed out, and under the conditions prevailing at this installation would yield about 0.09% of nitrogen in the gas. No other sources of nitrogen in the gas are apparent, except atmospheric contamination, and ordinarily such contamination is effectively excluded in this installation.

Methane.—Samples of the gas were passed through a train of caustic potash absorbers to remove the carbon dioxide, and the density of the residual gas was determined. The density of pure methane relative to air is 0.5544. Eleven determinations of the density of the methane fraction gave values from 0.562 to 0.577, with no consistent differences between the different stages. The average is 0.5678, 2.4% greater than the density of pure methane. The higher hydrocarbons known to be present should raise the density of the methane fraction about 0.6 per cent. The remainder of the effect is doubtless due to various other unindentified constituents.

SUMMARY AND CONCLUSION

(1) Results of a 4-yr study of the operation of a four-stage digestion system disclose that, with a nominal detention time of about 12 days, a reduction of 47% of the organic matter added was achieved. The sludge produced dried satisfactorily without odor or fly nuisance, and showed no appreciable difference in drying characteristics when compared with sludge digested three times as long.

(2) The results are also quite conclusive in determining that agitation by mechanical equipment is not needed in separate sludge digestion.

(3) Controlled seeding of raw solids with digested sludge, as accomplished in the multi-stage process, may be a factor in efficient digestion.

(4) The design of the tanks permitted a large accumulation of scum without reducing the efficiency of the system.

(5) The survey reveals that no appreciable liberation or absorption of heat occurred during the digestion process.

(6) The presence of relatively large quantities of iron salts in the sludge appears to have no deleterious effect upon the digestion process, and is beneficial in holding the concentration of hydrogen sulfide in the gas to a very low value.

(7) No nitrogen is lost in the digestion process. A portion is converted into soluble form and appears in the sludge liquor. The quantity remaining in the solids is approximately proportional to the organic matter remaining.

(8) The gas from the first stage is not substantially inferior to gas from the other stages as regards utilization for fuel; 47% of all gas was produced in the first stage.

DISCUSSION

Edward W. Moore,[12] Esq. (by letter).—In that it not only treats of an interesting development in the technique of sludge digestion, but also pioneers in the application of certain principles of physical chemistry to the study of the behavior of digesting sewage sludge, this paper appeals to the writer as a particularly valuable contribution to the literature of sludge digestion. The value of the concepts and methods of physical chemistry to the practising engineer is as yet recognized too infrequently.

Another physio-chemical concept which yields fruitful results when applied to the decomposition of organic matter both under aerobic and anaerobic conditions is that of reaction velocity. The course of the decomposition of organic matter under both aerobic and anaerobic conditions can be formulated approximately as a uni-molecular reaction, the rate of which is given by a constant, k, known as the reaction velocity constant. For aerobic decomposition at 20° C, k has a value of 0.1, as shown by the work of Professor Earl B. Phelps, Victor L. Streeter, Jun. Am. Soc. C. E., E. J. Theriault, and others. The writer, in collaboration with G. M. Fair, M. Am. Soc. C. E., has been engaged in collecting data from which the value of k for anaerobic decomposition at various temperatures may be computed. For 85° F the value of k obtained from the data thus far collected, is 0.066 for digestion of sludge seeded with material previously digested at this temperature. From the bottle experiments made by the authors, the ultimate total gas production of the Los Angeles sludge may be assumed to be about 625 cu cm per gram of volatile matter, and the volume produced (say, in 10 days' detention time) is 485 cu cm. From these data and assumptions a value of $k = 0.065$ is indicated.

It is of interest to the writer to note that, in sludge digestion studies, two questions perpetually recur, namely, the relationship between the weight of the gas produced and the weight of the volatile matter destroyed, and the evolution or absorption of heat by the reactions of digestion. The authors find that the weight of the gas produced is 7% more than the weight of the volatile matter destroyed, despite the fact that their total gas production per unit of volatile matter added to the tanks is very low (485 cu cm per gram of volatile matter added). The work of A. M. Buswell and his associates,[13] and that of Professor Fair, and the writer[14] has indicated that the weight of the gas may exceed the weight of the volatile matter destroyed by as much as 28 per cent. This increase in the weight of the decomposition products over the weight of the original material is explained by Buswell as due to the fact that water enters into the reactions by which the gas is formed. Willem Rudolfs, M. Am. Soc. C. E.,[15] has held that the weight of the gas does not exceed that of the volatile matter destroyed.

Sludge digestion consists of a complex of reactions, some of which are exothermic (heat-evolving) and others endothermic (heat-absorbing). The over-all heat effect (that is, the actually observed heat absorption or evolution during the course of digestion) is the sum of the effects of the individual reactions. The work of Messrs. Keefer and Kratz showing the over-all process to be endothermic was based on a few experiments in which gas production per unit of volatile matter was relatively high. Prior work by Professor Fair, and the writer had indicated on theoretical grounds that since the endothermic reactions of the digestion process were concerned with dissolution and evolution of the gas, the over-all process would be expected to be endothermic when gas production per unit of volatile matter added was high, and exothermic when it was low. The results reported in the paper would be expected to be exothermic rather than endothermic on account of the low gas yield.

Despite the layer of lime scale formed on the heating pipes of the digestion tank, the value of the coefficient of heat transfer from water to sludge is about 13 Btu per hr, per sq ft of pipe surface per degree of temperature differential, which is as good as most values reported in practice. It would be of interest to know the average temperature of the hot water entering the coils, since this is believed to control the degree of incrustation of the pipes. It would also be interesting to calculate the heat transfer coefficient from the tank to its surroundings from the data following Table 7 and the surface area of the tank, since the matter of the rate of heat loss from digestion tanks still requires considerable study.

Some sludge digestion studies have indicated the presence of hydrogen and carbon monoxide in the gas produced. No dependable evidence of the presence of these gases in significant quantities has been obtained in the Harvard University laboratories, although hundreds of analyses have been made. The very delicate methods used by the authors show only traces of these gases, and, as the authors state, do not definitely establish their presence. It is possible that much of the hydrogen and carbon monoxide reported in sludge digestion studies is due to errors in the determination of methane by combustion. The determinations of hydrogen sulfide are of practical as well as theoretical interest, since the corrosiveness of the combustion products of the gas is determined largely by the quantity of hydrogen sulfide it contains. The writer believes that some of the sulfur present in the gas evolved from digesting sewage sludge is present in the form of organic homologues of hydrogen sulfide, particularly in the case of thermophilic digestion. Some of the foul odors carried by these gases cannot be accounted for by the presence of such small percentages of hydrogen sulfide.

The fact that none of the nitrogen contained in the digesting sludge appears in the gas as elemental nitrogen is confirmed also by the results of the Harvard studies on sludge digestion. This conclusion, however, cannot be extended to the decomposition of other organic deposits, such as those found on the bottoms of lakes and streams. Studies of the decomposition of such deposits by Allgeier, Peterson, Juday, and Birge[16] and by Professor Fair and the writer,[17] indicate the production of substantial quantities of nitrogen gas. Since these deposits are similar to partly digested sludges, the radical difference in the behavior of the two materials has not as yet been explained.

[17] *Civil Engineering,* December, 1937, p. 846.

The disappearance of phosphate from the sludge liquor during the second test period (see Table 9), might possibly be accounted for by absorption of the phosphate by organisms carried down with the solid matter of the sludge. Bio-chemists often use the decrease in soluble phosphate as a measure of the growth of organisms in a medium.

WILLEM RUDOLFS,[18] M. AM. SOC. C. E., AND H. HEUKELEKIAN,[19] ESQ. (by letter).—The attempt to make use of the observed phenomenon of automatic segregation of solids during digestion by withdrawing particles of digested sludge from the bottom and allowing the more active mass to remain longer in the tanks is of unusual interest. It is well known that a portion of properly seeded fresh solids is rapidly decomposed, another portion will sink to the bottom of a tank, and still another part of the fresh solids (including fatty material, hair, match sticks, soap, etc.) remains floating for a considerable time while undergoing decomposition. Withdrawal of the material segregated at the bottom causes a gradual increase in the quantity, and frequently in the density, of the floating mass. This inherent behavior of the sludge is well illustrated by the authors in Fig. 4. Inability of the scum to move with the separated sludge to the next tank results in scum formation and this material may stay in the primary, secondary, or even tertiary tank for a long time, while the inorganic and partly digested solids pass on. This method of segregation is undoubtedly theoretically correct, because it permits the material most difficult to digest to remain longest in the tanks. On the other hand, the method results automatically in increasing quantities of scum in the first tanks, unless the digestion time allowed is ample to take care of the accumulating mass, or distribution of sludge; that is, unless so-called sludge circulation is practiced. If the digestion time is insufficient the mass of scum eventually becomes so large that the capacity of the tanks is reduced materially and the scum must be taken care of by other means. The results graphically shown in Fig. 4 seem to indicate that after twenty-five months of operation the capacities of Tanks 1, 2, and 3 had been reduced (on account of scum formation) by 25 to 30 per cent. The tanks were emptied and cleaned, and it would be of interest to know what was done with this scum, which apparently digested actively when placed in suitable containers.

Of considerable interest is the fact that the average solids content of the new sludge pumped to the digesters was 4.7 per cent. The sludge mixtures consisted of 33% of primary and 67% of activated sludge by volume. This rather high solids concentration may be a contributory factor for the short digestion period in the digesters. In considering the short digestion period of 10.3 to 13.5 days, the open pits, serving as balancing reservoir, storage tank, and secondary digestion unit, are of importance. The scum formation, occasional foaming, and density of the subnatant and supernatant liquors indicate that the digesters were pushed to the limit and occasionally, possibly, beyond the limit. The foaming probably caused by the combination of using occasional poorly digested sludge for seeding and rapid gasification in some of the units, is perhaps the best indication of over-loading, together with the fact that supernatant liquor removal was promoted in the pits after storage.

---

[18] Prof. and Head of Depts., Water Supplies and Sewage Disposal, Rutgers Univ.; and Chf., Div. of Water and Sewage Research, State Agri. Experiment Station, New Brunswick, N. J.

[19] Associate, Div., Water and Sewage Research, State Agri. Experiment Station, New Brunswick, N. J.

The fact that good digestion results were obtained during the short digestion period in the tanks, followed by after-digestion in the pits, is of practical interest, but is not surprising. Similar results have been obtained elsewhere in the laboratory, in pilot plant trials, and in full-scale plant operation. Where no after-digestion facilities were available, sooner or later the difficulty was to produce persistently a rapidly draining, digested sludge. In a large part of the country open-air drying of sludge, which retains its moisture tenaciously, is limited to summer or to warm, dry seasons. The importance of secondary digestion should not be over-looked and, admittedly, it is a factor in the case under discussion. The over-all results obtained in the tanks, a reduction of 46 to 47% of volatile matter, indicate satisfactory digestion. This fact, together with the separation of water in the storage pits, seems to leave no doubt that the process utilized was successful as far as volatile matter reduction and gasification were concerned.

Actively digesting masses of sludge do not show temperature stratifications. The mass is in constant movement and, as has been stated previously, fresh and actively digesting solids entrain gases more readily than old or digested solids. The proportion of solids carried up by entrained gas depends, therefore, on the relative quantities of fresh solids. In an actively digesting mass of sludge the solid particles are in constant motion, either up or down, depending upon whether or not they carry entrained gas, so that the liquid and its contents are in a state of dynamic equilibrium. Since the sludge masses in the tanks were constantly stirred by the gas formation and the flow of sludge from tank to tank, only little, if any, temperature stratification would be expected. In cases where sludge is digested and stored in a single tank, the picture is different, depending upon the mass of actively digesting material and the capacity of the tank. When the storage capacity of the tank is large and considerable quantities of ripe sludge are retained, temperature stratification is likely to be encountered.

The data submitted on heat transfer, although limited, are of interest. The difference of 500 000 Btu between the heat applied and the heat required to raise the temperature of the new sludge was only 3.6% of the total heat input. Without having detailed results it is difficult to state how much of the loss can be accounted for by experimental error. Unfortunately, no results are available for possible radiation losses. The information on this phase of the problem is scarce, but seems to indicate that the difference in free-heat content of the raw and digested sludge and its subtraction from the total heat input, could be accounted for by radiation losses.

The general statement of the authors, that the 25% of sludge wasted directly from the digestion tanks to the drying beds showed no difference in drying characteristics from the 75% of sludge pumped from the pits, does not show what the cause was of the "rather erratic results, indicating considerable variation in drainability of sludge from time to time." In general, the 4.5% sludge lost about one-half its moisture in 48 hr. Extensive investigations with partly and well-digested sludges have shown that the quantity of water drainable on sand beds during the first 24 hr varies greatly with the degree of digestion. Well-digested sludge (52% solids) loses as much as 85% of its total moisture (at 74° F) by drainage, and the remainder is lost by evaporation. With increasing temperatures, evaporation increases. The drainage from incompletely digested solids is much less and slower. Even when 80% of the possible gas production has evolved, drainability is comparatively slow, amounting to from 40 to 50% of the total moisture content in 24 hr.

Nitrogen balances made some years ago[20] showed that there was no reduction in the total nitrogen content during digestion of sewage solids. On the basis of original solids the percentage of nitrogen increases in the digested sludge on account of the decomposition and loss of other materials into gases. The authors reach the conclusion that "the digestion of nitrogenous matter roughly parallels the digestion of other organic matter, with the result that the percentage nitrogen in the solid organic matter does not show any great change." This is similar to the conclusion reached previously. As the authors state, this does not mean that the nitrogen in the raw sludge does not undergo transformation, converting the insoluble nitrogen into soluble forms. During digestion, active hydrolysis of nitrogenous materials in the sludge takes place, resulting in an increase in ammonia, amino acids, and other soluble forms of nitrogen. The possibility of liberation of nitrogen gas from organic matter under anaerobic conditions does not seem great. Nitrates, if present, would be reduced, under anaerobic conditions, with the liberation of nitrogen gas. Nitrogen may also be formed by the interaction of nitrites with amino acids, but under anaerobic conditions neither nitrates nor nitrites could be produced. The loss of nitrogen from digesting tanks really occurs by the discharge of supernatant liquor, containing the various soluble nitrogen compounds. A second, and material, loss occurs when the digested sludge is placed on sand drying beds. The soluble nitrogenous materials disappear with the water drained. If these soluble nitrogenous materials could be retained, the digested sludge would have considerable value as a fertilizer. Activated sludge contains more nitrogen because a large part of the soluble nitrogen is transformed into protoplasmic nitrogenous substances, but the loss of total organic matter is less. When the soluble nitrogenous substances are retained in digested sludge, the nitrogen content should not only be higher on the basis of dry solids, but the nitrogen would be more available for plant food. At present, processes are known and in operation by which at least a part of the soluble nitrogen can be held in the digested sludge.

The outstanding contribution of the work presented by the authors is that with proper operation an apparent digestion schedule of fifteen days can be maintained at a temperature of 85° F, utilizing a system of multi-stage digestion for the gradual and partial destruction of organic solids, producing the usual quantities of gas, leaving a drainable residue, without undue difficulties in operation.

---

[20] *Industrial Engineering Chemistry*, Vol. 20, p. 177 (1928).

Short digestion periods are of practical interest and may be obtained with modifications in environmental conditions. With the present state of knowledge the most important environmental factor for properly seeded sludge is temperature. When the temperature is raised high enough to obtain thermophilic digestion, the time required is materially reduced, but the principal disadvantage is that the sludge digested in a period of a few days does not de-water as rapidly as well-digested mesophyllic sludge. Results obtained on a system consisting of consecutive digestion at high temperature (130° F) for a few days, the digestion at low temperatures (80 to 85° F) for the destruction of remaining finely divided material and compacting of sludge, indicate that this is a practical and economical plan. Such a method must include adequate stirring mechanisms to obtain consistently good results. In a system of multi-digestion units, the basic principles of decomposition are not different from single-stage, two-stage, or consecutive digestion. It becomes mainly a question of economics of construction and operation, therefore, to determine which system should be chosen. The fact that the authors have shown that short-time digestion periods can be obtained with a multi-stage digestion unit, which does not require excessively careful operation, is of practical importance to those who must select a system. The greater the variety of methods, the wider the scope.

HERMANN BACH,[21] ESQ. (by letter).—The authors have rendered valuable work in contributing to the bio-chemical and physico-chemical reactions involved in the digestion of sewage sludge. The idea of stages, especially, is basically appealing as it is obvious that the more complicated a process is the more easily it may be simplified by sub-dividing it into convenient working stages, planned so as to favor the particular factor or factors segregated in each stage. In planning such stages, the designer should avoid the temptation of sub-dividing the process into more parts than may be justified economically, in order that the advantages of the separate stages may not be overbalanced or canceled by excess construction costs or unreasonably high operating cost. This kind of foresight is amply evident in the authors' description of the treatment plant constructed for the Los Angeles County Sanitation District. Although two-stage sludge digestion plants using a separate tank construction for each stage are in common use, the authors' description of a four-stage digestion system is remarkable not only because of the multiple stages, but also because, in solving the construction problem, the designers have avoided separate digesters for each stage, by confining the four stages to one structure. This device cleverly avoids the danger of excess first cost and increased operating cost.

The paper raises a logical question as to the number of stages that may actually be necessary in a given case. In the present case, why were there four instead of three, or five, or eight stages? It seems impossible, theoretically, to predict the number of stages that would be most advantageous and, therefore, one must be content to trust his judgment from the results obtained after the plant has been in operation. Selecting gas production as a "yardstick," the data presented in Table 5 afford an opportunity to determine the extent to which the Los Angeles plant has fulfilled expectations. Placing the total gas production (see last column of Table 17) as 100% of the "technical digestion range" (that is, omitting from consideration, the potential surplus of gas production listed in Table 6), the percentage of gas production by stages will be as shown in Table 17. Thus, the proportion of gas production (that is, the digestion work output in Stages 1 to 4) appears to be 1 : 0.46 : 0.40 : 0.36. Since the capacities of the four compartments are equal, whereas Table 17 indicates that the output is not equal (it is less in each stage), the base sub-division in the over-all tank apparently is not consonant with the relative efficiency of the four stages. Whereas, the sub-divisions were made equal in capacity, Table 17 indicates that, relatively, they should have been in the proportion of 1 : 2.1 : 2.48 : 2.8, with the capacity of the first stage assumed equal to 1. In the reverse order, with the fourth stage assumed equal to 1, the relative subdivisions should have been 0.36 : 0.75 : 0.89 : 1. The dimension of each compartment in that case would have been proportional to the efficiency of the separate stages, thus fully justifying the construction cost.

TABLE 17.—AVERAGE PRODUCTION OF GAS, LOS ANGELES COUNTY SANITATION DISTRICTS, CALIFORNIA

Units	Stage 1	Stage 2	Stage 3	Stage 4*	Total, Stages 1 to 4
Thousands of cubic feet per day	125.3	59.3	50.4	45.4	280.0
Percentage of total	45	21	16	18	100

* The tanks in Stage 4 were only partly filled; the values given in Table 5 were computed as for full tanks.

The need for increasing the dimensions of the compartment in a multiple digestion plant is due to the fact that, in the first period, the sludge decomposes very quickly. As shown in Table 5, after the new sludge in Stage 1 has been substantially decomposed, there is a sudden decrease in the digestion rate, after which subsequent digestion is at a comparatively slow rate tapering to a point beyond which it ceases to be within the "technical digestion range" (a term proposed by Dr. Karl Imhoff). As far as possible, these peculiarities of the material dealt with should be given appropriate consideration in designing the structures for multiple-stage digestion.

The difference in gas production between Stages 3 and 4 is so slight as to indicate that the rate of decomposition had become uniform in each of them. Consequently, it may be unnecessary to construct more than three compartments if the third compartment is made proportionately larger than the first two. On the other hand, however, the more stages that are provided, the greater the opportunity will be for the plant to profit by the "gravimetric segregation," which is an exceedingly valuable feature of the process described in the paper. Indeed, this action may be, to a large extent, the explanation for the astonishingly short time period required to prepare the sludge for the drying bed.

Table 6 indicates that the sludge leaving the last digestion compartment is still capable of producing about 80% more gas if the digestion is extended to approximately twice that of the preceding four stages. It is to be regretted that this volume of gas is lost, which also raises the question as to whether the sludge has actually been digested sufficiently if it still contains some organic substance capable of such gas production. On the other hand, gas production is not the principal purpose of sludge digestion, the gas being only a by-product. The principal purpose, really, is to convert the sludge into a form that can be readily disposed of without creating a nuisance. As this objective seems to have been attained satisfactorily in a brief time at the Los Angeles plant, the designers were probably not justified in providing for an extension of the process merely to produce gas. Furthermore, there would be the potential danger that prolonged digestion would make the sludge too thick to handle in the pumps and on the sludge bed.

Scum Accumulation.—Scum is formed by fat particles which, because of their low specific weight, rise to the surface, carrying other particles with them. The percentage of fat and oil in raw sewage depends on local conditions such as the characteristic food consumed, the presence of industrial plants, automotive traffic, etc. The percentage of fatty material may vary greatly from plant to plant and within the same plant, from season to season. The intensity of scum formation in the sludge digestion tanks may vary accordingly. The so-called mineral oils, such as lubricating oil and grease, gasoline, etc., are highly resistant to bacterial decomposition. Nevertheless, the various fats of animal and plant origin, including the fat contained in greases, are very susceptible to anærobic decomposition, being an important source of sludge gas production as shown in Table 12. To produce and maintain such an anaerobic bacterial action, two conditions are necessary: Sufficient moisture and isolation from the atmosphere. In digestion tanks of the usual construction, including the Los Angeles plant described in this paper, these two conditions are not fulfilled satisfactorily. As may be noted in Table 3, the scum is too dry, containing less than 85% moisture. Such relatively small water content makes the unrestrained action of bacteria more or less difficult. In addition, the scum is freely exposed to the "air." Although, in this particular case, the "air" is not the freely circulating atmosphere, it is sludge gas, which is highly unfavorable to bacterial action because it is made up of products of bacterial metabolism.

In order to accelerate the digestion of fatty substances which form scum layers, means should be provided for moistening the scum throughout its total mass, and preventing its contact with circulating atmosphere or with sludge gas. An improvement in the process of draining the sludge could be devised by placing an elevated sludge tank between the digester or the sludge pit and the sand bed, thus making it possible to discharge the sludge on the bed by gravity. Pumping releases the gas from the sludge, thus raising its specific gravity. The result is that the particles drop quickly to the sand, clogging it against the supernatant. This unfavorable condition may be remedied by retaining the pumped sludge in the elevated tank for an additional digestion period of a half day or so. When the sludge has regained some gas content and is then discharged on the sand bed, the sludge will drain better as its particles will show a tendency to remain on top while the free water below flows through the filter.

The writer was especially interested in Table 9 which contains some very instructive data, the form in which phosphorous occurred is peculiar indeed. Some years ago, the writer observed a surprisingly high phosphate content in the scale deposited on heating coils in a separate sludge digestion tank operated as a whole at mesophilic temperatures. In investigating this strange case, he concluded that the thermophilic bacteria thriving in the immediate vicinity of the heated coils absorb phosphorous compounds to a higher degree than do the mesophilics in the remaining part of the digestion tank. After the thermophilic bacteria on the surfaces of the coils had died, there remained a residue accumulating slowly and being converted to mineral phosphates. It would be interesting to know whether a similar condition occurs in the scale deposited on the heating coils of the plant described by the authors.

C. E. **Keefer**,[22] M. Am. Soc. C. E. (by letter).—A group of interesting experiments is reported in this paper, which should stimulate further investigations of the separate digestion of sludge. It would appear that the type of tanks used, which permitted the segregation of the solids into scum and settled material with facilities for seeding the raw sludge and digesting the material in several stages, was partly responsible for the unusually rapid digestion obtained. It is hoped that further experiments will be conducted with a similar type of tank in some other locality in order to compare and check the results.

A study was made of the heat added to the digestion tank for a period somewhat less than a month. The authors calculated that the heat added to the sludge was 13 900 000 Btu per day, and that the heat required for radiation and endothermic requirements was 1 200 000 Btu daily. Based on some laboratory experiments conducted by Herman Kratz, Jr. and the writer,[4] the authors calculate that the endothermic requirements alone would be 3 690 000 Btu, a quantity three times as great as the heat available for this purpose. They also state that the fall in temperature of the sludge from the second to the fourth tank was less than 0.5° F, whereas it should have been 2.3° F if the findings of Mr. Kratz and the writer were correct.

It is unfortunate that the authors have not given more of the data upon which their calculations are based. It would be interesting to know how the temperature in the tanks was obtained, how many thermometers were used in each tank, and the location of each of them. What type of thermometer was used? and to what degree of accuracy could they be read? The statement that the difference between the average temperatures of the second and the fourth tanks was less than 0.5° F would, in general, seem to be open to considerable question. It is doubtful whether the average temperature of the sludge in a digestion tank of any appreciable size can be obtained within 2° to 4° F as there is usually a considerable difference of temperature in various parts of the tank. Sludge in the zone immediately adjacent to heating coils will often be from 40° to 60° F hotter than the incoming cold sludge. Sludge near the walls and the bottom of a tank far removed from heating coils will be cooler than the sludge near the coils. To obtain accurate results a large number of thermometers would be required. The complexity of the problem can be appreciated when it is remembered that it is difficult to keep the temperature in specially designed and well-insulated constant-temperature rooms that are thermostatically controlled and provided with means such as fans to prevent the stratification of air within much less than 1° F. As it is much more difficult to determine the average temperature of sludge in a digestion tank, there is considerable question as to the advisability of drawing conclusions regarding the endothermic requirements of sludge digestion from large-scale experiments.

[22] Prin. Asst. Engr., Bureau of Sewers, Baltimore, Md.

[4] "The Interchange of Heat During Sludge Digestion," by Messrs. C. E. Keefer and Herman Kratz, Jr., *Sewage Works Journal*, Vol. 5 (1933), p. 3.

It would seem wiser to conduct experiments of this special nature in a calorimeter, in which the temperature can be determined within about 0.001° C. The disadvantage of such an investigation is that a small quantity of the sludge must be used.

In discussing the alleged difference in the results obtained in the laboratory at the sewage works at Baltimore and at the disposal plant near Harbor City, Calif., it should be stated that the Baltimore sludge was from a preliminary sedimentation tank, whereas the material from the latter plant contained 67% activated sludge. Furthermore, more seeding sludge was used at Baltimore. The fact that the Baltimore sludge digested much more slowly may have had a bearing on the difference in the results.

A. M. RAWN,[23] M. AM. SOC. C. E., A. PERRY BANTA,[24] ASSOC. M. AM. SOC. C. E., AND RICHARD POMEROY,[25] ESQ. (by letter).—Replying to Mr. Moore's question about water temperature in the heating coils: When the rate of heat conductance was 13 Btu per hr, per sq ft of pipe surface per degree Fahrenheit of temperature differential, the test records show that the temperature of heating water into and out of the heating coils was 180° and 143° F, respectively. After the coils were cleaned and the conductance rate was 54 Btu, the temperatures were 151° and 113° F, respectively. The writers' observations confirm Mr. Moore's comment that higher temperatures of the circulating water accelerate lime deposit on the coils. Design data for the District tanks contemplated a maximum temperature in the coils of 135° F, but the tanks are handling more than twice the sludge originally contemplated, and it is necessary to raise the circulating water temperature correspondingly.

The writers deemed it impractical to attempt to derive coefficients of heat loss through the outside tank walls, as suggested by Mr. Moore, because the gross heat loss of 1 200 000 Btu per day includes, inseparably, the radiation losses and the endothermic (or exothermic) requirements of the bacterial process. The mild climate of California further complicates the problem.

Mr. Keefer questions the temperature measurements. The quantity of heat added to the sludge by the heating water was determined by metering the flow, and by measuring the temperature of the water entering and leaving the tanks, with a mercury thermometer that could be inserted into the stream at several locations. Temperatures were read to 0.5° F and averages of sixteen days were taken. It is believed that the error in the value for heat input is probably less than 3 per cent. Temperature of the raw sludge was assumed to be the same as sewage temperature, the latter being read three times daily.

[24] Asst. Engr., Los Angeles County Sanitation Dists., Los Angeles, Calif.

[25] Research Chemist, Los Angeles County Sanitation Dists., Los Angeles, Calif.

Temperatures in the tanks are read daily to the nearest degree by means of thermo-couples placed near the middle of one of the side bays of each tank. In the first tank there is some uncertainty as to the values due to local temperature differences, as presented by Mr. Keefer; consequently, these values are not relied upon in attempting to ascertain the heat effect of the process. However, the differences are not great, as Table 7 shows. When the measurements in Table 7 were made, readings were also taken at three depths in the west bay of Tank No. 1, Battery A, at a distance of 1 ft from the heating coils, giving values of 85.2°, 85.2°, and 86.8° F. The average is only 2.1° higher than at the middle of the bay, accounted for by agitation due to vigorous digestion, and to the absence of extensive stratification of solids at that time (see Fig. 4(*b*)).

Concerning the second, third, and fourth stages, the rapid flow of the sludges, the vigorous digestion, and the fact that no heat was added and little was lost, are reasons for believing that the temperature must have been quite uniform throughout those tanks. Hence, the routine thermo-couple readings are probably representative of the average temperatures. Sixty-six readings in the third and fourth stages, taken during the period of the heat-effect study, all showed 85° F. In the second stage there were twenty-seven readings of 85° F, four of 86° F, and one of 87° F. Thus, the indicated loss from the second to the fourth stage was 0.19° F; but since a consistent effect as great as 0.5° might escape notice, it was reported that the fall in temperature "was less than 0.5° F."

The estimated difference in free heat between the raw sludge and the digested sludge depends upon the raw sewage temperatures, the temperatures in the fourth tanks, and the measurements of the quantity of sludge pumped. The latter quantity was obtained from pressure readings, and thus represents the actual weight of sludge pumped, free from any error due to entrained gas. Seeding had no effect upon these calculations, since seed was taken from the fourth tank. It is believed that the error in the free-heat difference is probably less than 10 per cent. On the basis of experimental error, it would be very difficult to account for the difference between the possible endothermic effect in this digestion system and the results of Messrs. Keefer and Kratz.

It was not intended that any question should be cast upon the validity of the results reported by Messrs. Keefer and Kratz. As has been noted in the discussions by Mr. Moore and by Mr. Keefer, different behavior in respect to the heat balance may be expected from different sludges. The data were presented to contribute some further information obtained under different conditions. Unfortunately, the data do not allow an exact evaluation of the heat effect, since the heat lost to the surroundings cannot be determined.

The results do show that the process was not accompanied by an endothermic effect as large as that observed by Messrs. Keefer and Kratz.

The writers wish to minimize the significance of the greater weight (7%) of gas produced when compared with the weight of organic matter destroyed. The observational basis of the indicated difference is weak and, therefore, the experimental error may be relatively large. Furthermore, this value (7%) takes no account of the carbon dioxide, ammonia, and volatile acids lost from samples of new or digested sludge upon drying during analysis. The theoretical basis of such a difference is well established but the derived value (7%) should not be considered a precise empirical value.

Regarding scum accumulation, Messrs. Rudolfs and Heukelekian state: "If the digestion time is insufficient the mass of scum eventually becomes so large that the capacity of the tanks is reduced materially and the scum must be taken care of by other means." That this situation does not apply to the installation under discussion is witnessed by the digestion experiments conducted on samples of the scum. It was found that, for the first four days after removal from the tank, scum from the first stage produced gas at a rate of 5.0 liters of gas per liter of scum, whereas the highest measured rate of gas production from the first stage taken as a whole was 3.11 liters of gas per liter of sludge (see Table 5). It seems quite likely that after twenty-five months of operation, conditions regarding scum accumulation may be considered static (see Fig. 4). Tanks were emptied because of the condition of the heating coils, not because of scum accumulation.

No pronounced difference has been noted in the drainability of sludge from the tanks and from the pit. Detail results are at hand relating to fourteen beds of sludge drawn during the period of these tests. Five beds from the pit, averaging 4.49% solids, lost from 16% to 37% of their water in 16 hr, the average loss being 28 per cent. Nine beds from the tanks, averaging 4.77% solids, lost an average of 26% of their water in the same length of time—the slight difference being in the direction that would be expected from the variation in solids content. No explanation is apparent for the erratic variation of individual beds.

Exactly at what point a sludge is "well-digested" is a moot question. The writers believe that a well-digested sludge is one that drains and dries without attendant nuisance, in a reasonable length of time. Freedom from nuisance in drying seems to be closely connected with the content of volatile organic acids. Experience at the plant under discussion indicates that sludge that has less than 200 ppm of volatile acids can be placed on the drying beds with positive assurance that it will not breed house flies and that there will be no objectionable odors. As for drainability, it is doubtless true that, in general, prolonged digestion will produce a sludge which drains rapidly. However, in a separate sludge digestion system it is not economical to aim for the ultimate in·drainability. Sludge beds are usually cheaper than digestion tanks.

In Mr. Bach's discussion of the optimum relative size of stages in a digestion system, the writers do not concur in the desirability of proportioning the stages so that an equal volume of gas is produced from each stage. Admittedly, there is little technical information on which to base the choice and, in the installation under discussion, judgment and operating and structural considerations have dictated.

Mr. Bach has misinterpreted Column (7) of Table 6. This column was meant to indicate that, of all the gas produced in the digestion tanks, plus the gas produced with 21 days additional detention time, about 83% was produced in the tanks and 17% was produced in the 21 days of additional detention time.

Scum at this plant contains entrained sludge particles, seeds, matches, hair, bits of rubber, and other light débris. The fact that the moisture content is only 85% and that the surface is in contact with sludge gas does not seem to inhibit active digestion as is suggested by Mr. Bach. That it is the seat of active digestion has been demonstrated previously. The sludge gas is saturated with moisture and has no drying effect.

EARTHQUAKE STRESSES IN AN ARCH DAM

BY IVAN M. NELIDOV[1] AND HAROLD E. VON BERGEN,[2]
ASSOC. MEMBERS, AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. A. FLORIS, CECIL E. PEARCE, F. W. HANNA, A. W. FISCHER, RAY L. ALLIN, AND I. M. NELIDOV AND H. E. VON BERGEN

SYNOPSIS

The forces of inertia manifested in a structure during an earthquake are ordinarily taken into account in the design. In this paper formulas are derived for determining the stresses due to the horizontal effect of an earthquake on an arch dam for two different conditions: First, the acceleration of the earthquake is assumed to occur along the canyon, that is, horizontally up stream; and, second, the acceleration is assumed to occur across the canyon, that is, horizontally at right angles to the first condition. The vertical effect of the earthquake is omitted from consideration because of its minor importance. Arches with hinged ends as well as with fixed ends are considered, and illustrative numerical examples are given (see Table 1). The derivation of the formulas is based on Castigliano's Theorem of Least Work.

INTRODUCTION

Stresses in thin circular arches due to water load have been investigated at length, but not much has been written of the stresses induced by an earthquake in the arch due to its own inertia. In this paper an attempt is made to investigate these stresses and to find their relative importance in the design of an arch dam. Algebraic symbols are defined where first introduced and are assembled, for convenience of reference, in the Appendix. The formulas derived are for moments, thrusts, and shears induced in an arch by an earthquake for two conditions: (1) Acceleration is assumed to occur along the canyon; and (2) it is assumed to occur across the canyon.

Assumption (1) Applied to Arches with Fixed Ends.—Consider an element within an arch ring, 1 ft deep and having an elementary weight, dW, equal to (see Fig. 1):

$$dW = w_c \, t \, r \, d\theta \quad \text{.......................(1)}$$

in which w_c = unit weight of concrete, in pounds per cubic foot; t = uniform

[2] Asst. Hydr. Engr., State Dept. of Public Works, Sacramento, Calif.

radial thickness of the arch, in feet; and r = the radius of the center line of the arch, in feet. With the earthquake acting horizontally and the plane of the arch ring inclined at an angle, ψ, with the vertical, as in the case of a multiple arch, the elementary force, dP, exerted upon each arch element in the plane of the arch ring will be,

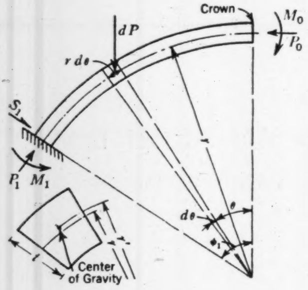

FIG. 1

$$dP = \frac{a}{g}\,dW \sin\psi \ldots\ldots\ldots (2)$$

in which a is the acceleration of the earthquake, and g is the acceleration of gravity. The force, dP, acts through the center of gravity of the arch element, which lies slightly outside the neutral axis at a distance, r', from the arch center. In this case, it can readily be shown that $r' = r\left(1 + \frac{k^2}{r^2}\right)$, in which k^2 is substituted for $\frac{t^2}{12}$. Since, for the symmetrically loaded arch, there is no rotation of the crown section under load and no translation of the crown section in the direction of the crown thrust, the partial derivatives of Castigliano's equation for internal elastic work with respect to the crown moment, M_0, and the crown thrust, P_0, are equal to zero.[3] The derivation of the formulas for moment, thrust, and shear for this case is similar to that for the dead load of the arch,[3] and is omitted herein.

With the introduction of r', $\frac{a}{g}$, $w_c' = w_c \sin\psi$, and $C = \frac{a}{g}\,w_c'\,t\,r$, the thrust, moment, and shear at the crown are, respectively,

$$P_0 = C\,Z' \ldots\ldots\ldots (3a)$$

$$M_0 = C\,r\,Z_2' \ldots\ldots\ldots (3b)$$

and,

$$S_0 = 0 \ldots\ldots\ldots (3c)$$

and at the abutments,

$$P_1 = C\,Z_1' \ldots\ldots\ldots (4a)$$

$$M_1 = C\,r\,Z_3' \ldots\ldots\ldots (4b)$$

and,

$$S_1 = C\,Z_4' \ldots\ldots\ldots (4c)$$

in which,

$$Z' = \left[2\left(1 + \frac{r'}{r}\right)\frac{\sin^2\phi_1}{\phi_1} - \frac{\sin 2\phi_1}{2}\left(\frac{5}{2} + \frac{r'}{r}\right) + \frac{\phi_1 \cos 2\phi_1}{2} - \phi_1\frac{r'}{r} + (2.88 - 1)\frac{k^2}{r^2}\left(\frac{\sin 2\phi_1}{4} - \frac{\phi_1\cos 2\phi_1}{2}\right)\right] \div \left[\left(1 + \frac{k^2}{r^2}\right)\left(\phi_1 + \frac{\sin 2\phi_1}{2}\right) - \frac{2\sin^2\phi_1}{2} + \frac{2.88\,k^2}{r^2}\left(\phi_1 - \frac{\sin 2\phi_1}{2}\right)\right] \ldots\ldots\ldots (5)$$

---

[3] "Stresses in Inclined Arches of Multiple Arch Dams," by George E. Goodall and Ivan M. Nelidov, Assoc. Members, Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 1208.

and,

$$Z_1' = Z' \cos \phi_1 + \phi_1 \sin \phi_1 \ldots\ldots (6a)$$

$$Z_2' = \left(Z' + \frac{r'}{r}\right)\left(1 - \frac{\sin \phi_1}{\phi_1}\right) - \frac{\sin \phi_1}{\phi_1} + \cos \phi_1 \ldots\ldots (6b)$$

$$Z_3' = \left(Z' + \frac{r'}{r} + 1\right)\left(\cos \phi_1 - \frac{\sin \phi_1}{\phi_1}\right) + \phi_1 \sin \phi_1 \ldots\ldots (6c)$$

and,

$$Z_4' = \phi_1 \cos \phi_1 - Z' \sin \phi_1 \ldots\ldots (6d)$$

Assumption (1) Applied to Arches with Hinged Ends.—The derivation of the formulas for moment, thrust, and shear for this case is similar to that for dead load, as previously mentioned, except, again, for r', $\frac{a}{g}$, $w_c' = w_c \sin \psi$, and C. The moment, thrust, and shear at the crown are, respectively,

$$P_0 = C\, Z'' \ldots\ldots (7a)$$

$$M_0 = C\, r\, Z_2'' \ldots\ldots (7b)$$

and,

$$S_0 = 0 \ldots\ldots (7c)$$

and at the abutments,

$$P_1 = C\, Z_1'' \ldots\ldots (8a)$$

$$M_1 = 0 \ldots\ldots (8b)$$

and,

$$S_1 = C\, Z_4'' \ldots\ldots (8c)$$

in which:

$$Z'' = \left[\frac{3}{4}\sin 2\phi_1 + \frac{3\, r' \sin 2\phi_1}{2\, r} - \phi_1\left(\frac{3}{2}\cos 2\phi_1 + \phi_1 \sin 2\phi_1 + \frac{r'}{r}(2 + \cos 2\phi_1)\right) + (2.88 - 1)\frac{k^2}{r^2}\left(\frac{\sin 2\phi_1}{4} - \phi_1 \frac{\cos 2\phi_1}{2}\right)\right]$$
$$\div \left[\phi_1(2 + \cos 2\phi_1) - \frac{3}{2}\sin 2\phi_1 + \frac{k^2}{r^2}\left(\phi_1 + \frac{\sin \phi_1}{2}\right) + \frac{2.88\, k^2}{r^2}\left(\phi_1 - \frac{\sin 2\phi_1}{2}\right)\right] \ldots\ldots (9)$$

and,

$$Z_1'' = Z'' \cos \phi_1 + \phi_1 \sin \phi_1 \ldots\ldots (10a)$$

$$Z_2'' = \left(Z'' + \frac{r'}{r}\right)(1 - \cos \phi_1) - \phi_1 \sin \phi_1 \ldots\ldots (10b)$$

and,

$$Z_4'' = \phi_1 \cos \phi_1 - Z'' \sin \phi_1 \ldots\ldots (10c)$$

In the foregoing equations, if $\frac{r'}{r} = 1$, the value of Z' and Z'' will be identical to those derived[3] elsewhere for the dead load of the arch. For a ratio, $\frac{t}{r} = 0.3$, the value of $\frac{r'}{r} = 1.0075$ and decreases with the decrease of $\frac{t}{r}$, which indicates the error involved by such a substitution.

Assumption (2) Applied to Arches with Fixed Ends.—It is assumed for this case that the acceleration of the earthquake is from right to left, acting parallel to a line drawn through the abutments. The forces producing deformation in the arch ring, induced by the inertia of each elementary part of the arch, act toward the right, opposite in direction to that of the acceleration.

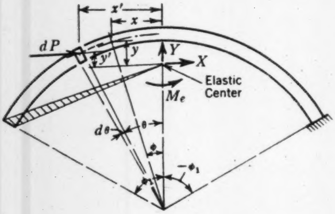

FIG. 2

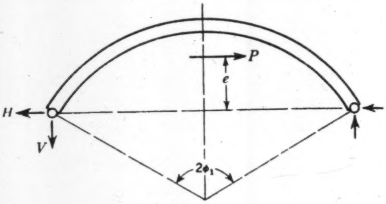

FIG. 3

Since the loading on the arch ring is not symmetrical about the crown and, therefore, the rotation and translation of the crown section are unknown, it is necessary to consider the entire arch ring (see Fig. 2). Assume the arch ring to be fixed, at its right abutment, to the canyon wall, and the left abutment to be held by an imaginary rigid bracket connected to the elastic center of the arch and kept stationary by the forces, X and Y, and the moment, M_e. For a circular arch ring of uniform thickness the elastic center lies at the center of gravity of the neutral axis.

The total internal elastic work in the entire arch ring is:

$$W = \int_{-\phi_1}^{\phi_1} \frac{M^2\,ds}{2\,E\,I} + \int_{-\phi_1}^{\phi_1} \frac{P^2\,ds}{2\,E\,A} + 2.88 \int_{-\phi_1}^{\phi_1} \frac{S^2\,ds}{2\,E\,A} \quad \ldots\ldots\ldots (11)$$

and since there is no rotation or translation of the rigid bracket at the elastic center the partial derivative of the work with respect to X, Y, and M_e is equal to zero, or:

$$\frac{\partial W}{\partial X} = \int_{-\phi_1}^{\phi_1} \frac{M}{E\,I} \frac{\partial M}{\partial X} ds + \int_{-\phi_1}^{\phi_1} \frac{P}{E\,A} \frac{\partial P}{\partial X} ds + \frac{2.88}{E\,A} \int_{-\phi_1}^{\phi_1} S \frac{\partial S}{\partial X} ds = 0 \ldots\ldots (12a)$$

$$\frac{\partial W}{\partial Y} = \int_{-\phi_1}^{\phi_1} \frac{M}{E\,I} \frac{\partial M}{\partial Y} ds + \int_{-\phi_1}^{\phi_1} \frac{P}{E\,A} \frac{\partial P}{\partial Y} ds + \frac{2.88}{E\,A} \int_{-\phi_1}^{\phi_1} S \frac{\partial S}{\partial Y} ds = 0 \ldots\ldots (12b)$$

and,

$$\frac{\partial W}{\partial M_e} = \int_{-\phi_1}^{\phi_1} \frac{M}{E\,I} \frac{\partial M}{\partial M_e} ds + \int_{-\phi_1}^{\phi_1} \frac{P}{E\,A} \frac{\partial P}{\partial M_e} ds + \frac{2.88}{E\,A} \int_{-\phi_1}^{\phi_1} S \frac{\partial S}{\partial M_e} ds = 0 \ldots (12c)$$

At any radial section in the arch ring (x, y), the moment, thrust, and shear are,

$$M = M' + Xy + Yx + M_e \ldots\ldots\ldots\ldots\ldots\ldots (13a)$$

$$P = P' + X \cos\phi + Y \sin\phi \ldots\ldots\ldots\ldots\ldots (13b)$$

and,

$$S = S' + X \sin\phi - Y \cos\phi \ldots\ldots\ldots\ldots\ldots (13c)$$

in which M', P', and S' are the moment, thrust, and shear at the section (x, y), produced by the external loads on the arch ring to the left of the section. From Equations (13),

$$\frac{\partial M}{\partial X} = y \qquad (14a)$$

$$\frac{\partial M}{\partial Y} = x \qquad (14b)$$

$$\frac{\partial M}{\partial M_e} = 1 \qquad (14c)$$

$$\frac{\partial P}{\partial X} = \cos \phi \qquad (15a)$$

$$\frac{\partial P}{\partial Y} = \sin \phi \qquad (15b)$$

$$\frac{\partial P}{\partial M_e} = 0 \qquad (15c)$$

and,

$$\frac{\partial S}{\partial X} = \sin \phi \qquad (16a)$$

$$\frac{\partial S}{\partial Y} = -\cos \phi \qquad (16b)$$

$$\frac{\partial S}{\partial M_e} = 0 \qquad (16c)$$

Substituting Equations (13) to (16) in Equations (12), and solving for X, Y, and M_e, the results are as follows:

$$-X = \frac{\int_{-\phi_1}^{\phi_1} \frac{M'}{I} y\, ds + \int_{-\phi_1}^{\phi_1} \frac{P' \cos \phi}{A} ds + 2.88 \int_{-\phi_1}^{\phi_1} \frac{S' \sin \phi}{A} ds}{\int_{-\phi_1}^{\phi_1} \frac{y^2\, ds}{I} + \int_{-\phi_1}^{\phi_1} \frac{\cos^2 \phi\, ds}{A} + 2.88 \int_{-\phi_1}^{\phi_1} \frac{\sin^2 \phi\, ds}{A}} \qquad (17a)$$

$$-Y = \frac{\int_{-\phi_1}^{\phi_1} \frac{M'}{I} x\, ds + \int_{-\phi_1}^{\phi_1} \frac{P' \sin \phi\, ds}{A} - 2.88 \int_{-\phi_1}^{\phi_1} \frac{S' \cos \phi\, ds}{A}}{\int_{-\phi_1}^{\phi_1} \frac{x^2}{I} ds + \int_{-\phi_1}^{\phi_1} \frac{\sin^2 \phi\, ds}{A} + 2.88 \int_{-\phi_1}^{\phi_1} \frac{\cos^2 \phi\, ds}{A}} \qquad (17b)$$

and,

$$M_e = \frac{\int_{-\phi_1}^{\phi_1} \frac{M'\, ds}{I}}{\int_{-\phi_1}^{\phi_1} \frac{ds}{I}} \qquad (17c)$$

It is now necessary to find the values of M', P', and S', so that they may be substituted in Equations (17). The force acting on each element of the arch through its center of gravity, induced by the earthquake, is,

$$dP = \frac{a}{g}\, dW = \frac{a}{g}\, w_c\, t\, r\, d\theta = C\, d\theta \ldots\ldots\ldots\ldots\ldots (18)$$

and the mathematical summation through the angle, $\theta = \phi$ to $\theta = \phi_1$ of these forces, times their respective lever arms, and the mathematical summation of the proper components, will produce M', P', and S', the moment, thrust, and shear, respectively, of the "external" loads at the point, x, y. Since:

$$x = r \sin \phi \ldots\ldots\ldots\ldots\ldots (19a)$$

$$x' = r' \sin \theta \ldots\ldots\ldots\ldots\ldots (19b)$$

$$y = r\left(\cos \phi - \frac{\sin \phi_1}{\phi_1}\right) \ldots\ldots\ldots\ldots\ldots (19c)$$

$$y' = r' \cos \theta - r\, \frac{\sin \phi_1}{\phi_1} \ldots\ldots\ldots\ldots\ldots (19d)$$

then,

$$dM' = C\, r\left(\cos \theta - \frac{r'}{r} \cos \theta\right) d\theta \ldots\ldots\ldots\ldots\ldots (20)$$

and,

$$M' = C\, r\left[(\phi_1 - \phi) \cos \phi - \frac{r'}{r}(\sin \phi_1 - \sin \phi)\right] \ldots\ldots (21a)$$

Likewise,

$$P' = C \cos \phi\, (\phi_1 - \phi) \ldots\ldots\ldots\ldots\ldots (21b)$$

and,

$$S' = C \sin \phi\, (\phi_1 - \phi) \ldots\ldots\ldots\ldots\ldots (21c)$$

Substituting Equations (21) into Equations (17), replacing ds by $r\, d\phi$, and integrating:

$$X = -\, C\, \phi_1 \ldots\ldots\ldots\ldots\ldots (22a)$$

$$\begin{aligned} Y = -\, C\, \phi \Bigg[&\left(\frac{1}{2} - \frac{\sin 2\phi_1}{4\phi_1} - \sin^2 \phi_1\right)\left(1 + \frac{k^2}{r^2} - 2.88\, \frac{k^2}{r^2}\right) \\ &+ \frac{r'}{r}\left(1 - \frac{\sin 2\phi_1}{2\phi_1}\right)\Bigg] \div \Bigg[\left(\phi_1 - \frac{\sin 2\phi_1}{2}\right)\left(1 + \frac{k^2}{r^2}\right) \\ &+ 2.88\, \frac{k^2}{r^2}\left(\phi_1 + \frac{\sin 2\phi_1}{2}\right)\Bigg] = -\, C\, C_Y \ldots\ldots\ldots (22b) \end{aligned}$$

and,

$$M_e = -\, C\, r\left(1 - \frac{r'}{r}\right) \sin \phi_1 \ldots\ldots\ldots\ldots\ldots (22c)$$

Transfer the forces, X and Y, and the moment, M_e, to the abutment and the following moments, thrusts, and shears in the arch are obtained:

At the crown ($\phi = 0$),

$$M_0 = 0 \ldots\ldots\ldots\ldots\ldots (23a)$$

$$P_0 = 0 \ldots\ldots\ldots\ldots\ldots (23b)$$

and,

$$S_0 = -\, C\, C_Y \ldots\ldots\ldots\ldots\ldots (23c)$$

At the left abutment ($\phi = \phi_1$),

$$M_1 = C\,r \left[\left(\frac{r'}{r} - C_Y \right) \sin \phi_1 - \phi_1 \cos \phi_1 \right] \qquad (24a)$$

$$P_1 = C\,(-\,\phi_1 \cos \phi_1 - C_Y \sin \phi_1) \qquad (24b)$$

and,

$$S_1 = C\,(-\,\phi_1 \sin \phi_1 + C_Y \cos \phi_1) \qquad (24c)$$

and, at the right abutment ($\phi = -\,\phi_1$),

$$M_2 = -\,M_1 \qquad (25a)$$

$$P_2 = -\,P_1 \qquad (25b)$$

and,

$$S_2 = S_1 \qquad (25c)$$

Assumption (2) Applied to Arches with Hinged Ends.—In the case of an arch with hinged ends (and also with fixed ends), it may be readily proved that $P = 2\,H$ (see Fig. 3) in which P is the total force induced by the earthquake acting through the center of gravity of the arch. The problem of finding the stresses in a hinged arch is then rendered statically determinate. From Fig. 2,

$$P = 2\,\frac{a}{g}\,w_c\,t\,r\,\phi_1 = 2\,C\,\phi_1 \qquad (26a)$$

$$H = C\,\phi_1 \qquad (26b)$$

$$e = r'\,\frac{\sin \phi_1}{\phi_1} - r \cos \phi_1 \qquad (26c)$$

and,

$$V = \frac{P\,e}{2\,L} \qquad (26d)$$

in which L = one-half the span length. The moment, thrust, and shear for any value of ϕ within the arch is,

$$M = M' - H\,r\,(\cos \phi - \cos \phi_1) + V\,r\,(\sin \phi_1 - \sin \phi) \qquad (27a)$$

$$P = P' - H \cos \phi - V \sin \phi \qquad (27b)$$

and,

$$S = S' - H \sin \phi + V \cos \phi \qquad (27c)$$

At the crown ($\phi = 0$):

$$M_0 = 0 \qquad (28a)$$

$$P_0 = 0 \qquad (28b)$$

and,

$$S_0 = C\left(\frac{r'}{r} - \phi_1 \cot \phi_1 \right) \qquad (28c)$$

At the left abutment ($\phi = \phi_1$):

$$M_1 = 0 \qquad (29a)$$

$$P_1 = -C\,\frac{r'}{r}\sin\phi_1 \qquad (29b)$$

and,

$$S_1 = C\,\phi_1\left(\frac{r'\cos\phi_1}{r\,\phi_1} - \frac{1}{\sin\phi_1}\right) \qquad (29c)$$

and, at the right abutment ($\phi = -\phi_1$):

$$M_2 = 0 \qquad (30a)$$

$$P_2 = -P_1 \qquad (30b)$$

and,

$$S_2 = S_1 \qquad (30c)$$

Numerical Example.—Assume an arch with a thickness, $t = 19$ ft; mean radius, $r = 171$ ft; central angle, $2\,\phi_1 = 103°$; and depth of water, $h = 70$ ft. Let: $\frac{a}{g} = 0.1$; $w_c = 150$ lb per cu ft; $r' = r$; and $\psi = 90$ degrees.

The stresses due to uniform water load are computed from known formulas[4] to serve as a basis for comparison to the earthquake stresses, as shown in Table 1. The stresses designated as s_e, s_i, and s_s are combined bending and direct stresses at the extrados and the intrados of the arch and shear stresses, respectively.

TABLE 1.—COMPARISON OF EARTHQUAKE STRESSES, IN POUNDS PER SQUARE INCH

(The minus sign indicates tension)

Load	CROWN			LEFT ABUTMENT			RIGHT ABUTMENT		
	Extrados, s_e	Intrados, s_i	Shear, s_s	Extrados, s_e	Intrados, s_i	Shear, s_s	Extrados, s_e	Intrados, s_i	Shear, s_s
(*a*) ARCH WITH FIXED ENDS									
Uniform water load	341	127	0	33	447	−14	33	447	14
Earth acceleration along the canyon	26	2	0	18	26	− 2	18	26	− 2
Earth acceleration across to canyon	0	0	3	−104	80	−11	104	−80	−11
(*b*) ARCH WITH HINGED ENDS									
Uniform water load	353	217	0	286	286	−27	286	286	27
Earth acceleration along the canyon	27	3	0	22	22	2	22	22	2
Earth acceleration across to canyon	0	0	5	−14	−14	− 9	+14	14	− 9

CONCLUSIONS

The example chosen represents an arch ring at about the mid-height of an average arch dam and is assumed to be a typical one. It will be noted that an earthquake which accelerates the dam up stream produces stresses that seldom exceed about 10% of the water-load stresses; but for an earthquake acting across the canyon the stresses from this cause may be quite large. Of course, these stresses do not include the possible restraining effect of adjacent arch rings, but this effect would probably tend to reduce their magnitude, as the trial-load method of analysis indicates for water-load stresses.

---

[4] "The Circular Arch Under Normal Loads," by the late William Cain, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., LXXXV (1922), p. 233.

Furthermore, it will be noted by observation that the less the central angle is, the less vulnerable will be the arch for the cross-wise acceleration. Therefore, it is fortunate perhaps that the thick lower parts of some arch dams subtend a much smaller central angle than the thin upper parts.

APPENDIX

NOTATION

The following symbols, defined where first introduced in the paper, are rearranged herein for convenience of reference. An effort has been made to conform essentially with "Symbols for Mechanics, Structural Engineering, and Testing Material"[5] compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

a = linear acceleration of an earthquake;

C = a coefficient (see Equations (3)); C_Y = coefficient, C, when forces are translated to the elastic center of the arch (see Equation (23c));

e = eccentricity; lever arm of Load P, measured vertically from the springing;

g = acceleration due to gravity;

I = moment of inertia;

k = a constant ratio $= \frac{t^2}{12}$;

L = one-half the span length of an arch;

M = moment; M_1 = bending moment at the springing due to the elemental external load, dP; M_c = bending moment at the crown, due to the elemental external load, dP; M_e = bending moment translated, and assumed acting at the elastic center of an arch; and M' = moment at the section, x, y, produced by the external loads on the arch ring to the left of the section;

P = a concentrated force; total force induced by an earthquake, acting through the center of gravity of the arch; P_1 = the normal thrust at the springing due to an elemental external load, dP, on the arch; P_c = the normal thrust at the crown due to an elemental external load, dP, on the arch; and P' = the thrust at the section, x, y, produced by the external loads on the arch ring to the left of the section;

---

[5] A S A—Z10a—1932.

p = pressure per unit area; pressure due to the head, y; p_0 = pressure due to the head, h_0;

r = radius of the center line of the arch; r_e = radius of the extrados of an arch; r_i = radius of the intrados of an arch; and r' = radial distance to the center of gravity of an arch element;

S = shearing component; S_1 = total shear at the springing; S' = shear at the section, x, y, produced by the external loads on the arch ring to the left of the section;

s = stress; s_e = combined direct stress and bending at the extrados; s_i = combined direct stress and bending at the intrados; and s_s = shear stress;

t = uniform, radial thickness of an arch;

W = total, internal, elastic work;

w = unit weight of water; w_c = unit weight of concrete; and w_c' = component unit weight of concrete = $w_c \sin \psi$;

X = horizontal load assumed acting at the elastic center of an arch;

Y = vertical load assumed acting at the elastic center of an arch;

Z = a coefficient; also Z' and Z'' (see Equations (3) to (10), inclusive);

θ = polar co-ordinate; angular distance; angle between the tangents to the arch ring, at the crown and any point; and $d\theta$ = angle between the radial sides of an elemental segment of an arch of depth, t;

ϕ = the central angle of an arch; ϕ_1 = one-half the central angle of an arch;

ψ = inclination of the plane of the arch ring.

DISCUSSION

A. Floris,[6] Esq. (by letter).—Earthquake stresses produced in an arch dam slice, fixed or hinged at the abutments, but free to move laterally, are analyzed in this paper. Only the influence of the inertia forces of the arch is taken into account, those of the water behind the dam and of the canyon walls being omitted. Under these simplifying assumptions the seismic analysis of the structure is complete.

However, the question arises as to whether such an analysis can be considered as criterion of the seismic resistance of an arch dam. It is true that buildings are analyzed for earthquake shocks by considering their inertia forces only. These structures are usually free to move in all directions above the ground, the resistance of the air being negligible. In an arch dam the inertia force of water, in view of the lightness of the structure, is an important item. In buildings, the dead and live loads are the gravity forces that mainly determine the design. The weight, the only gravity force exerted by arch dams, is neglected in the stress analysis as unimportant. The available theories pertaining to the influence of water upon the dam, presuppose a straight structure with a vertical up-stream face, true only in the case of a gravity dam.[7] Moreover, the arch dam is enclosed in the narrow canyon between the mass of rock. What will be the effect of all the surrounding inertia forces upon the dam? The present analysis fails to yield an answer.

Bearing these limitations in mind, the paper may be judged as an interesting contribution to the aseismic design of arch dams.

Cecil E. Pearce,[8] Assoc. M. Am. Soc. C. E. (by letter).—The effects of earth shock upon an arch dam are analyzed in this interesting investigation. It has ordinarily been stated by enthusiasts that an arch dam can take an earthquake overload better than any other type because all that results is a slight increase in compression, with no alarming effects in regard to sliding or overturning, and the claim is probably correct. These statements refer to an earthquake in which the dam is accelerated up stream.

However, when the direction of the acceleration is at right angles to the stream, the results are different. The authors have shown that these effects are more serious than the up-stream acceleration usually investigated. This checks the statement made by Mononobe:[9]

> "The effect of earthquake upon ordinary masonry dams is most pronounced when the transverse seismic wave propagates parallel to the longitudinal axis of the dam. The seismic wave causes a forced displacement around the perimeter of the dam's base. If the body of the dam is of one mass, the different parts of the dam's foundation bed exercise relative displacements.

I, p. 275; and "Water Pressure on Dams During Earthquakes," by H. M. Westergaard, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 418.

[8] Senior Hydr. Engr., TVA, Knoxville, Tenn.

[9] "Earthquake-Proof Construction of Masonry Dams," by Nagaho Mononobe, M. Am. Soc. C. E., World Eng. Congress, Tokyo, Japan, 1929.

This will cause to develop vertical and horizontal crosswise cracks and leakage due to separation of the base of the dam from the bed rock. To remedy these defects and to prevent excessive stresses, vertical crosswise joints or expansion joints may be employed."

Mononobe further suggested that the contraction joints be spaced far enough apart so that the different blocks of the dam can be made stable against accelerations in the direction parallel to the longitudinal axis. In high dams, however, this procedure would conflict with the spacing requirements of contraction joints dictated by shrinkage coincident with the cooling of the concrete.

It would seem that the worst case would be for neither of the two conditions investigated by the authors but for the condition of reservoir empty and an acceleration of the dam down stream. For flood control reservoirs (which should be empty as much as possible), and other reservoirs which are well drawn down part of the year, this case is about as likely to occur as the "reservoir-full" cases investigated. Without computation, it seems plausible that the relatively thin arch dam section would be far less stable against a down-stream acceleration than the top part of a gravity dam, because in this direction there is no arch action in the dam.

It should be emphasized that the formulas developed bear considerable resemblance to those developed by the late William Cain, M. Am. Soc. C. E.[10] The value 2.88 is recognized as the factor for the inclusion of the elastic work of shear.

The writer has computed and checked numerical values for such expressions as: $\phi_1\left(\phi_1 + \frac{\sin 2\,\phi_1}{2}\right)$; $2\sin^2\phi_1$; $2.88\,\phi_1\left(\phi_1 - \frac{\sin 2\,\phi_1}{2}\right)$; $2\sin\phi_1$; $\left(1 - \frac{\sin\phi_1}{\phi_1}\right)$; and, $\left(\frac{\sin\phi_1}{\phi_1} - \cos\phi_1\right)$, for every value of $2\,\phi_1$ from 1° to 180°, by 1° increments which appear in published form.[11] These values are listed in from five to seven decimal places, and are sufficiently accurate for machine computation. Their use shortens the work considerably.

It should always be borne in mind that although formulas such as those developed by the authors seem somewhat complicated at first glance, essentially, they are simply formulas for finding the bending moment, M (in a horizontal plane), and the horizontal thrust, P, at any point in the arch. With these values once obtained, the stresses may be calculated by the simple beam formula, $S = \frac{P}{A} \pm \frac{M\,c}{I}$, the notation for which needs no explanation.

F. W. HANNA,[12] M. AM. SOC. C. E. (by letter).—The effects of earthquakes on dams, of both the arch and the gravity types, are important in regions where earthquakes are prevalent. The authors have presented an important element for the determination of these effects in thin circular arches of uniform thickness both with fixed and with hinged ends. The solutions presented are capable of amplification and also of extension, of which the authors are no doubt aware.

[12] Cons. Engr., Ankeny, Iowa.

The earthquake impulse under Assumption (1) is assumed to act horizontally in a vertical plane parallel to the sides of the canyon and, therefore, parallel to a vertical plane through the crown of the arch rings of an arch barrel of the arch dam. The authors have treated only the down-stream impulse in their paper. This impulse may act either in a down-stream or in an up-stream direction.

For example let Fig. 4 represent a semi-section of a symmetrical ring of uniform thickness of a multiple-arch dam, the plane of the ring being inclined at an angle of ψ with the vertical. Let $C\,D$ be the trace, on the plane of the arch ring, of a vertical plane parallel to the vertical plane through the crown section of the arch ring. Assume the impulse of an earthquake shock to act horizontally either down stream or up stream on the arch in a direction parallel to this vertical plane. At the left of Point C in Fig. 5 is shown a down-stream impulse, dF, on an elementary volume of the arch ring, depicted in section in Fig. 4, resolved into its component forces, dR acting along CD in the arch ring and dN acting upward along the arch barrel, in the vertical plane.

Now, dR is resisted by arch action of the arch ring and dN is carried mainly by beam action of the arch ring to the adjacent piers and tends to overturn them down stream. Also, to the right of Point C in Fig. 5 are shown an up-stream impulse of dF on the elementary volume and its components, dR and dN. In this case also dR is resisted by the arch ring and dN is carried mainly by beam action to the adjacent piers and tends to weaken their resistance against overturning up stream. From these considerations it is evident that the algebraic signs of dF and dR (and, therefore, of the thrust, moment, and shear in the arch ring) are reversed for an earthquake acceleration acting up stream from those of one acting down stream. It also follows, therefore, that an arch ring designed for customary water pressure down stream is well suited to resist the stresses due to an earthquake shock with a down-stream accelera-

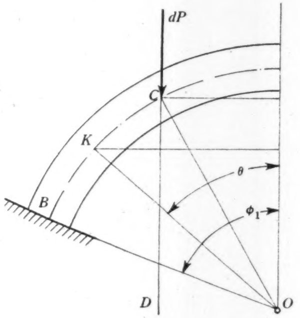

FIG. 4

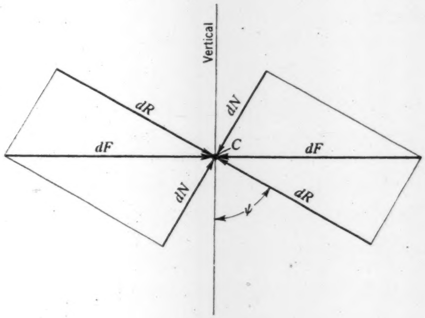

FIG. 5

tion; but that an arch ring so designed may not be suitable to resist stresses due to an earthquake shock with an up-stream acceleration. Steel should be introduced to take the tensional stresses produced by this latter kind of shock.

In the case of an earthquake acceleration parallel to the canyon walls, the force, F, in Fig. 5 will be different for each arch ring of an arch barrel depending on its position relative to the bottom of the arch. Neglecting the effects of the piers or canyon walls, the value of F for each arch ring may be computed approximately by the formula used for buildings[13] or for vertical slices of gravity dams.[14] For multiple or single arches relatively high for their lengths, the effects of the piers or canyon wall abutments are of considerable consequence. Impulses conveyed to a high single arch in a narrow canyon may even exceed that conveyed to it by the canyon floor and may be so great as to prevent the proper use of the building formula for finding the impulse force, F, for arch rings of different elevations. The stresses in such an arch would be more nearly approximated by considering it to be a plate supported on three edges.

In the case of an empty reservoir, the effects of earthquake shocks must be applied to the masonry of the structure only; but for a full or partly full reservoir the influence of the movement of the reservoir water on the masonry stresses must be taken into consideration. This subject has been treated in previous publications[15] and is referred to here only for the purpose of making the category of forces caused by earthquake shocks complete.

The authors have limited their considerations to thin circular arches, but the principle used in their analyses may readily be applied to thick circular arches and also to arches of variable thickness, both of the symmetrical and unsymmetrical types, merely by substituting the earthquake load for the usual water pressure and then following the analysis otherwise applicable. In this, as in all cases, it is best to avoid complications by assuming that r' is equal to r. The distance from the center of gravity of the arch ring is,

$$r' = \frac{\int_{r-\frac{t}{2}}^{r+\frac{t}{2}} r\,dr\,r\,d\phi}{\int_{r-\frac{t}{2}}^{r+\frac{t}{2}} dr\,r\,d\phi} = r\left(1 + \frac{t^2}{12\,r^2}\right) \text{.............} (31)$$

and, therefore,

$$\int \frac{r'}{r} = 1 + \frac{t^2}{12\,r^2} \text{.....................} (32)$$

For $r = 2\,t$, $\frac{r'}{r} = 1 + \frac{1}{48} = 1.002$, which is negligible in the face of the general uncertainties of the entire problem.

[13] "Reinforced Concrete and Masonry Structures," by Hool and Kinne, p. 600.

[14] "The Design of Dams," by Hanna and Kennedy, p. 109.

[15] "The Design of Dams," by Hanna and Kennedy, pp. 109–113; and "Water Pressures on Dams During Earthquakes," by H. M. Westergaard, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 98 (1933), pp. 418–472.

Solution of Equation (31).—Integrating,

$$r' = \frac{\int_{r-\frac{t}{2}}^{r+\frac{t}{2}} r\,dr\,r\,d\phi}{\int_{r-\frac{t}{2}}^{r+\frac{t}{2}} dr\,r\,d\phi} = \frac{\frac{d\phi}{3}\left[\,r^3\,\right]_{r-\frac{t}{2}}^{r+\frac{t}{2}}}{\frac{d\phi}{2}\left[\,r^2\,\right]_{r-\frac{t}{2}}^{r+\frac{t}{2}}} \ldots\ldots\ldots\ldots\ldots (33)$$

Canceling $d\phi$ and substituting limits,

$$r' = \frac{2}{3}\,\frac{\left(r^3 + \frac{3}{2}r^2\,t + \frac{3}{4}r\,t^2 + \frac{t^3}{8} - r^3 + \frac{3}{2}r^2\,t - \frac{3}{4}r\,t^2 + \frac{t^3}{8}\right)}{\left(r^2 + r\,t + \frac{t^2}{4} - r^2 + r\,t - \frac{t^2}{4}\right)}$$

$$= \frac{2}{3}\,\frac{\left(3\,r^2\,t + \frac{t^3}{4}\right)}{2\,r\,t} = \frac{2 \times 3\,r^2\,t\left(1 + \frac{t^2}{12\,r^2}\right)}{3 \times x\,r\,t} = r\left(1 + \frac{t^2}{12\,r^2}\right)$$

and, therefore:

$$\frac{r'}{r} = \left(1 + \frac{t^2}{12\,r^2}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (34)$$

Let r in the right member of Equation (34) equal $2\,t$; then $\frac{r'}{r} = 1 + \frac{1}{48} = 1.002$.

A. W. Fischer,[16] Esq. (by letter).—The subject of earthquake stresses is one of much importance to every engineer who designs structures in localities where earthquakes may occur, and the authors have contributed a valuable paper for calculating certain stresses in an arch dam.

The subject of earthquake stresses in an arch dam either hinged or fixed is treated at quite some length on the assumptions made by the authors and on their basis of calculations. The maximum stresses (as given in Table 1) are equal to ± 104 lb per sq in. for the arch with fixed ends. For the arch with hinged ends the maximum stress, as given in Table 1, is 27 lb per sq in., compression. The writer doubts if the stress given for the hinged-end condition is the maximum that could occur from an earthquake. Neglecting rib-shortening and assuming that due to an earthquake the abutment is displaced only 0.08 ft outward, and then substituting the values given in the numerical example (with $E = 3\,000\,000$ lb per sq in.), the fundamental equation for the horizontal thrust, on a slice 1 ft high, in a segmental two-hinged arch with a constant, I, is,

$$H = \frac{3\,000\,000\;(144)\;(1/12)\;(0.08)\;(19)^3}{(171)^3\;[(51.5/57.3)\;(2 + \cos 103°) - 1.5 \sin 103°]} = 29\,500 \text{ lb}$$

For the particular arch the moment at the crown equals 29 500 (171) vers 51° 30′ = 1 904 000 ft-lb, and from this moment the stresses at the crown equal ± 220 lb per sq in. The stress from direct load equals 11 lb per sq in., tension. The stresses are based on the assumption that the arch is a monolith and has no vertical expansion joints.

---

[16] Care, Construction Service, Veterans Administration, Washington, D. C.

Authorities might question the possibility of the abutment moving 0.08 ft, but the writer believes that in some localities this could happen and in extreme cases it could be greater than 0.08 ft, and stresses due to slight movements of the abutments should not be overlooked. The stresses in an arch dam with fixed ends will not be as large as in a two-hinged arch for the same displacement of the abutments; but in all arch dams, either two-hinged or with fixed ends, the stresses due to slight movement of the abutment should be considered.

RAY L. ALLIN,[17] ASSOC. M. AM. SOC. C. E. (by letter).—The earthquake effects on the stresses in an arch dam are clearly illustrated in this interesting paper.

Since, ordinarily, no tension can exist between a rock abutment and a concrete arch unless special anchorage has been provided, the cases noted by the authors must be for an arch, loaded prior to the earthquake shock with an intensity of compression stress greater than the intensity of tensile stresses indicated in the author's Table 1; or they must have assumed an equivalent compression distribution that will give the same moment and thrust at the abutment as those determined by the authors.

Where no arch thrust exists prior to earth shock, such as for an empty reservoir with horizontal arches, the case where the acceleration is acting parallel to a line through the abutments is similar to that where the arch is stood on one end with a body force equal to that due to earthquake acceleration. This case would place all the reaction at the abutment where the earth shock is transmitted to the dam, and would cause stresses of twice those values given by the authors at the corresponding abutment; and, at the crown, it would cause a direct thrust equal to one-half the abutment thrust, and a bending moment equal to the product of this crown thrust and its corresponding lever arm normal to the line through the center of gravity of each half of the arch. This case is not as vital to safety as that of a dam with full reservoir; yet it may be necessary to stiffen a slender arch to satisfy this condition.

Those engineers interested in the design of arch dams are indebted to the authors for their contribution on this subject of earthquake stresses in arch dams.

I. M. NELIDOV[18] AND H. E. VON BERGEN,[19] ASSOCIATE MEMBERS, AM. SOC. C. E. (by letter).—The several discussions have been gratifying in that they have expanded and clarified the work of the writers. Since many forces and actions come into play, and act upon a dam and its foundation and abutments during an earthquake, it is possible that the title of the paper has been somewhat misleading as to scope. It was the intention, however, to consider the fundamental force of inertia which is created whenever an earthquake tends to accelerate a structure in any direction. The writers consider only the single arch ring as a separate entity, being either a part of a single arch dam or a multiple-arch dam, realizing at the same time that yielding of abutments, stability of buttresses, differential movements of the abutments, hydrodynamic pressures, etc., must be considered to arrive at a complete solution of the problem.

---

[17] Hydr. Engr., Hetch Hetchy Project, San Francisco, Calif.

[18] Senior Engr. of Hydr. Structure Design, State Div. of Water Resources, Sacramento, Calif.

[19] Asst. Hydr. Engr., State Dept. of Public Works, Sacramento, Calif.

Although the hydrodynamic pressures on dams as proposed by Dean Westergaard[20] are not strictly applicable to arch dams, as stated by Mr. Floris, it may be possible to apply these forces to the face of an arch dam, by some rational method.

Mr. Pearce has directed attention to the unstable condition of a dam in the event of a down-stream acceleration with the reservoir empty. This is especially true for a single arch of the variable-radius design since a dam of this type often is provided with up-stream buttresses to prevent toppling up stream when the reservoir is empty even under static conditions.

The writers wish to express their appreciation to Mr. Hanna for clarifying the action of the elementary inertia force and its various components in the third and fourth paragraphs of his discussion and as shown in Figs. 4 and 5. Mr. Hanna has also described the use of the equations of moment, thrust, and shear for thick arches as well as thin arches. The error involved in substituting r' for r may be calculated from Equation (34). Another error involved is the appreciable displacement of the neutral axis as the $\frac{t}{r}$-ratio increases above 0.3.[21]

Mr. Fischer discussed the movement of an abutment which was somewhat beyond the scope of the paper. The yielding or movements of the abutments of an arch is a study in itself, not to mention the differential or relative movements of the two abutments during an earthquake.

Mr. Allin mentions the possibilities in the event of an empty reservoir during a lateral earth shock, when the abutments are unable to take tension. He rightly states the effect on the resisting abutment and the crown section and the resulting stresses. These conditions would have to be considered in the design and either special anchorage or increased strength provided.

In conclusion, the writers wish to thank those who have contributed discussions to the paper and thereby have enhanced its value. There is still much to be investigated in regard to forces and other phenomena produced by earthquakes which affect the stability of an arch dam.

GRAPHICAL REPRESENTATION OF THE MECHANICAL ANALYSES OF SOILS

By Frank B. Campbell,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Donald M. Burmister, A. J. Weinig, Carl H. Kadie, Jr., Carlton S. Proctor, T. T. Knappen, Jacob Feld, Howard F. Peckworth, Joel D. Justin, L. B. Olmstead, T. A. Middlebrooks, Frank E. Fahlquist and Waldo I. Kenerson, E. W. Lane, F. J. Sanger, F. Knapp, Charles H. Lee, and Frank B. Campbell.

Synopsis

In view of the lack of uniformity in proposals for the graphical representation of grain-size distribution, this paper is presented in an effort to correlate various existing methods and concentrate them into one method which the writer believes would make a good standard for graphical representation. A semi-logarithmic co-ordinate system is used with the grain sizes plotted as abscissas on a logarithmic scale and cumulative percentages by weight plotted as ordinates. With curves so plotted, the grain-size distribution curves have been conventionalized by introducing straight lines. Such lines can be designated briefly by their slopes and intercepts so that data from various soils may be tabulated or plotted on drawings for purposes of comparison. The value of mechanical analysis is discussed briefly. Further recommendation is made for nomenclature of soil fractions. In doing so there is an attempt to conform closely to the widely accepted classification used by the Bureau of Chemistry and Soils, United States Department of Agriculture, but to make the separations at recurring cycles of log 2 and log 6. Other classifications are also discussed.

Introduction

On considering the various types of soils which may be encountered in Nature, the writer has attempted to develop some simplified designation for both mean diameter and gradation of particle size. It is often desirable to adopt a set of symbols on a plan or profile which indicates the type of grain-size distribution. In the past, such drawings have usually indicated the soils as clay, sand, or gravel with many variations. Such descriptions depend upon

---

Note.—Published in December, 1937, *Proceedings*.

[1] Associate Engr., War Dept., U. S. Engrs. Office, Denison, Tex.

the conception of an individual as to the meaning of such terms. These conceptions vary widely. Sometimes, a set of symbols or numbers is used, in which case, a student of the drawing must learn a different system of designations each time he encounters a separate report. In certain studies, the engineer wishes to make a tabular comparison of a group of analyses of various samples. The method used in the past has been to list the quantity of each soil fraction, or to separate them in columns. Although the information thus recorded is definite, it is difficult for one to obtain a unified "picture" of the comparative grain-size distributions.

Mechanical Analyses Graphs

The importance of the mechanical analysis graph, or grain-size distribution curve, to technical literature lies in the fact that it is a method of international expression, or a universal language. The ordinate is the percentage by weight of the total sample, smaller than a corresponding particle diameter. Percentages involve no physical unit and are often called a ratio or a pure number. The millimeter is used as a unit of particle size. Technically trained men are familiar with the millimeter as a unit of length, and it proves to be a convenient scale for particle diameters of soils. The use of the English inch involves so many ciphers before the first significant figure as to be cumbersome. The purpose of the semi-logarithmic scale is obvious when the nature of grain-size distribution of soils is considered.

In discussing methods of graphical representation of the mechanical analysis of soils, other methods in occasional use should be mentioned. The older method of plotting the weight of soil separates or grain-size fractions, in percentages of the total weight, against particle diameter, has certain advantages of analysis as shown by Mr. Arthur J. Weinig,[2] in 1933. The tri-linear method of plotting mechanical analyses of soil is convenient for an approximate classification of soils according to texture. The method is explained by Messrs. R. O. E. Davis and H. H. Bennett.[3]

Recently some engineers have used repeating cycles of log 1, log 3, and log 5 for the abscissa lines. There is an increasing use in technical literature of log 2 and log 6. It should be noted that since $\log_{10} 2 = 0.301$ and $\log_{10} 6 = 0.778$, the scalar difference between successive abscissa lines is 0.477 and 0.523. These two scalar values offer a spacing of approximately equal distance as may be seen in Fig. 1.

The writer has plotted mechanical analyses selected from several hundred samples from widely different localities and types. Six types are shown in Fig. 1, as follows: Sample (*a*) is a black clay taken from the up-stream face of a dam which failed partly by sliding into the reservoir; Sample (*b*) is a red sandy clay that exhibits a broad variation of grain sizes; Sample (*c*) is an aeolian soil or "blow sand," and is a typical uniform grain-size material; Sample (*d*) represents a residual soil derived from sedimentary rock and has an excellent distribution of soil particles; Sample (*e*) is similar to Sample (*d*), except that it is coarser and indicates that the disintegration process has not been carried so far; and

[3] "Grouping of Soils on Basis of Mechanical Analysis," by R. O. E. Davis and H. H. Bennett, *Department Circular No. 419*, U. S. Dept. of Agriculture.

Sample (*f*) is a coarse gravel which contains some sand. It was selected from a dam that is quite stable, although it is very porous and continues to leak.

It should be mentioned that the shape of the mechanical analysis curve is often an indication of type; that is, whether it is residual, alluvial, or aeolian; and, if it is residual, the curve indicates its degree of maturity. The term, "residual," is used in the sense of a soil that has been derived by the disinte-

* Convexity is positive. † Estimated by extrapolation.

gration of igneous and certain metamorphosed rock. The shape of the curve may or may not be indicative of the degree of maturity of a soil derived from sedimentary rock. Certain alluvial and aeolian soils are difficult to classify as mature or immature from the standpoint of the disintegration process. In general, the principle follows that immature soils have a size distribution curve that is concave upward, and mature soils show a curve that is convex upward.

By the same reasoning, a soil that is represented by a straight line is often intermediate between maturity and immaturity. Such a soil usually contains particles ranging in size from clay to gravel. It should not be confused with soil of uniform grain size which is a vertical line on the graph. Such a soil is usually an alluvium or an aeolian type. Many observers have noted that water and wind are excellent sorting agents. In view of the foregoing facts, the writer believes that mechanical analysis graphs have a definite value in determining the history of a soil. It is often helpful to know the history of the soil development so that certain other chemical and physical characteristics may be anticipated and tests made for such qualities.

The need of a simplified classification according to grain size has often been recognized. The writer has attempted to develop one, first, by expressing the mean grain diameter, and second, by expressing the gradation of particle size according to the slope of the line on the mechanical analysis graph. The mean grain size is defined as that diameter, in millimeters, of which 50% of the sample by weight has larger diameters and 50% has smaller diameters. The gradation is assumed to be the slope of the straight line passing through the 20% smaller, and the 80% smaller, points of any one curve. The grade lines originating at the lower left-hand corner are shown in Fig. 1. A grade of 0 means that all particles have the same diameter. Grade 1 slopes from 0 to 100%, spanning one logarithmic cycle horizontally; Grade 2 spans two logarithmic cycles, etc. A decimal scale is shown along the top so that the grade may be read to tenths. The method is easily applied by two triangles for transferring the straight line through the 20% and 80% points to a parallel position through the origin at the lower left-hand corner of the graph. The grade can then be read from the horizontal scale at the top.

Table 1 shows the mean diameters and grades of the samples in Fig. 1. The letter designations of the curves on the graph are listed in the first column. The mean diameter is shown in the second column. The "Grade Line Deviation" is the difference between the curve and the grade line measured along the 50% ordinate. The writer has included this column to show the diameter difference, in millimeters, between the actual curve and the grade line. A minus deviation indicates a convex curve. However, the magnitude of the deviation is scarcely an indication of degree of convexity or concavity in a Cartesian sense, for the reason that the scale is logarithmic. The fourth column is the grade, or slope of the grade line, determined by the method described in this paper. The last column shows an abbreviated designation which includes both mean diameter, in millimeters, and the grade. Such a set of symbols may be utilized by plotting it on a soil map or profile.

Various nomenclatures of soil-size groups, or rather soil separates, are shown below the mechanical analysis graph. The most widely used classification is that of the Bureau of Chemistry and Soils, U. S. Department of Agriculture. Charles Terzaghi,[4] M. Am. Soc. C. E., has given a classification of soil separates in use in Germany. Recently, T. T. Knappen, M. Am. Soc. C. E., and R. R. Philippe,[5] Assoc. M. Am. Soc. C. E., have published a classification which they credit to the Massachusetts Institute of Technology. According to this classification, the upper limit of clay corresponds to that of the German "Schlamm." The classification advanced by the International Society of Soil Science is used by some soil scientists both in America and abroad.[6] The Society's Committee on Road Materials has defined the lower limit of sand as a 200-mesh Tyler sieve opening. Some engineers have adopted this conception. The Bouyoucos hydrometer times, corresponding to certain sizes, are shown. It serves to emphasize the lengthening interval of time involved in any sedimentation method when it is desired to determine the content of particles much smaller than 0.006 mm. The corresponding location of Tyler sieve openings illustrates the limits of screen analysis in common use. Mr. Weinig's[2] ordinal numerals are size groups developed for graphical analysis of soil separates. The coincidence of these size groups with the Tyler sieve openings may be seen. The uniform spacing of the Massachusetts Institute of Technology classification, Tyler sieve openings, and Weinig ordinal numerals on a logarithmic scale, are worthy of note.

The writer proposes a classification based upon the log 2 and log 6 division which is not widely different in nomenclature from the much used classification developed by the Bureau of Chemistry and Soils. Although similar to the Terzaghi and Massachusetts Institute of Technology classifications in the use of log 2 and log 6 divisions, the upper limit of clay is moved to 0.006 mm. Since the particles smaller than 0.0006 (the lower clay limit of the writer's classification) are beyond the limits of practical sedimentation analyses and ordinary microscopic technique, such fines should properly be relegated to the fields of colloidal chemistry and ultra-microscopy. For this reason, particles less than 0.0006 mm in diameter are termed colloids. By placing the upper limit of clay at 0.006 mm, fair agreement is had with the 0.005-mm limit of the Bureau of Chemistry and Soils, and the time required for sedimentation analysis is reduced to allow efficient laboratory working schedules. The proposed silt limits of 0.006 mm to 0.06 mm embrace practically all the silt class as defined by the Bureau of Chemistry and Soils, overlapping a little into very fine sand. The proposed fine, medium, and coarse sands correspond roughly to the Chemistry and Soils groups although the ranges are extended somewhat. The proposed coarse sand class overlaps the present fine gravel class, which has an upper limit of 2.0 mm. The new classification presented herein has the distinct advantage of facilitating the transfer of tabular data on soil separates to a mechanical analysis graph sheet for reproducing its curve.

ACKNOWLEDGMENTS

The writer expresses appreciation to E. W. Lane, M. Am. Soc. C. E., and other former associates in the Bureau of Reclamation, U. S. Department of the Interior, for curve data used in this discussion and to his present associates of the Soil Conservation Service, U. S. Department of Agriculture, for helpful criticism.

DISCUSSION

DONALD M. BURMISTER,[7] ASSOC. M. AM. SOC. C. E. (by letter).—The purpose of the mechanical analysis is two-fold: First, to determine and record the distribution of grain sizes of a soil; and, second, to interpret the results into terms of soil character. The author has given an excellent summary of the commonly recognized classifications of soil fractions or separates. The classification based on the log 2 divisions, which the author proposes, has certain decided advantages, because it is a continuation of the familiar Tyler sieve series.

In order to interpret the results of the grading analysis into terms of soil character, the size characteristics should be described in such a manner as not only to reveal the characteristic features of the soil, but also to yield practical information in relation to general soil behavior. Mr. Campbell has stated that the tri-linear chart, used by the U. S. Bureau of Public Roads, is a convenient one for the approximate classification of soils as to texture.

The most interesting and significant statement in the paper is that the shape of the grading curve is often an indication of whether the soil is of residual, alluvial, or æolian origin, and if it is found to be residual, the curve indicates the degree of maturity. The writer proposes to carry this significant and important fact to its logical conclusion in this discussion, and, therefore, wishes to present a line of reasoning[8] different from that usually followed in evaluating the grading analysis in terms of numerical values.

Although arbitrary definitions of the mean grain size are often convenient, such as the 50% size suggested by the author, or the familiar 10% effective size described by the late Allen Hazen, M. Am. Soc. C. E.,[9] yet such definitions must represent only temporary adaptations, which cannot be truly representative of such a diverse material as soil. A simple consideration of statistical principles will show that neither the median (50%), or the arithmetic mean can be used, logically, to define a characteristic mean for a semi-logarithmic plotting. An analysis[8] involving and extending the ideas of Krey, Kozeny, and Abrams shows that the degree of fineness of the soil may be expressed adequately by a mean grain size that is defined by the length of the equivalent rectangular area which is easily obtained by means of a planimeter or by simple summation of elementary areas, as shown in Fig. 2. This mean, which is the logical one to use for a semi-logarithmic plotting, takes the entire curve into account, and is actually a weighted geometric mean. It may be shown readily, that the mean grain size is also that having the geometric mean surface area. The most significant fact about the grading curve is that the area under it is a logarithmic function of the specific surface area of the soil analyzed. The importance of surface area, as particle size decreases, is recognized in the chemical and metallurgical industries, and practical use of this idea is made in the Gates "crushing surface diagram"[10] in ore-crushing operations.

[9] Annual Repts., Massachusetts State Board of Health, 1892.

[10] "The Handbook of Ore Dressing," by Taggart, p. 496.

It is further convenient to express the degree of fineness in terms of a size factor, as shown in Fig. 2, which is easily computed from the grading curve,

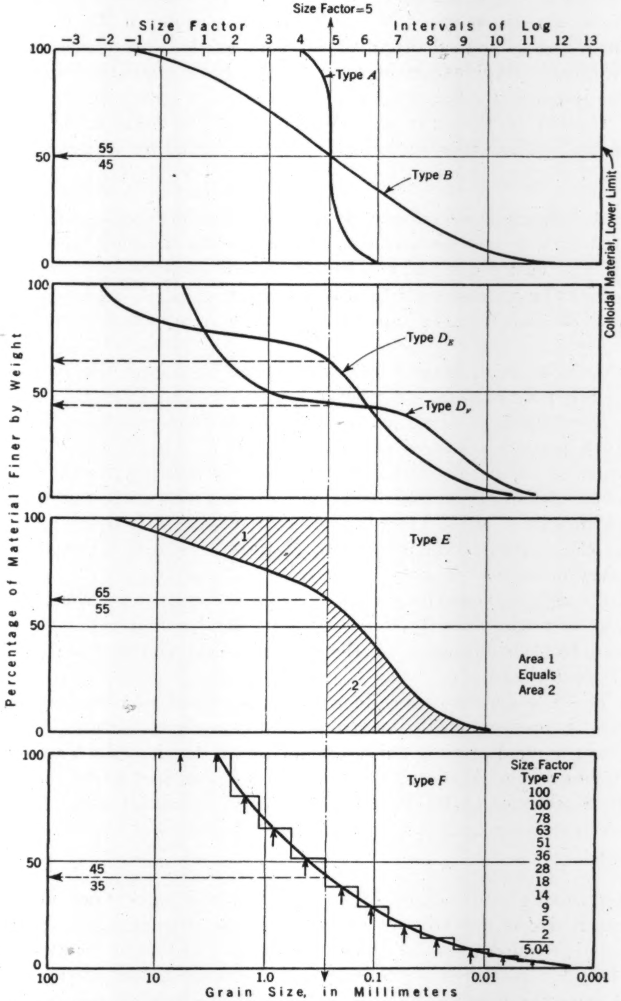

FIG. 2.—SIZE CHARACTERISTICS OF SOILS: (a) DEGREE OF FINENESS; (b) TYPE OF GRADING CURVE; AND (c) RANGE OF PARTICLE SIZES

the origin of this size factor designation of log 2 intervals being taken at the $\frac{3}{8}$-in. sieve, where there seems to be definite change in the capillary tendencies of soils. An advantage of the size-factor method is that the size factors of mixtures of soils may be easily obtained by simple proportion, the size factor as a logarithm being additive, and hence the mean size can be computed.

A description of grading curves as to type is proposed by the writer, based on statistical considerations. Not only does the shape of the curve give an indication of the geological origin of the soil, as the author suggests, but it also has a greater significance, because it furnishes a basis for correctly interpreting the important influence of the distribution of grain sizes on the density of soils, whether in the natural state, or placed in some artificial state in embankments. The classification as to type of grading curve is as follows (see Fig. 2):

Type A.—Single-size, narrow-range materials, or uniform materials are represented by a nearly vertical line on the grading diagram (these materials are always the least dense and can be compacted very little);

Type B.—The normal statistical distribution of particle sizes has a nearly symmetrical S-shaped curve (such soils can be compacted to quite a dense state);

Type C.—This is a straight-line distribution with equal proportions of all sizes (this is a poor grading; in general, less dense than Type B);

Type D.—This type is a mixture of two fractions, one fine and the other coarse (such materials have a decided hump in the grading curve; Type D_E is a mixture of some weathered or unweathered rock fragments in a matrix of much fine silty or clayey soil; and Type D_F is a mixture of much gravel and sand in a matrix of some very fine silty or clayey soil; these materials are typical of the so-called boulder clay of glaciated regions; they pack well and may be very dense);

Type E.—In this type the grading curve is skewed toward the fine fractions (that is, it is predominantly fine with some coarse material; the density is determined by the character of the fine material and is usually less than that of Type *B*); and,

Type F.—The grading curve in Type *F* is skewed toward the coarse fractions and is predominantly coarse with some fine material. This type approaches the ideal grading curve for maximum density (the Talbot grading) and conforms to the requirements for the best stabilized earth road mixtures of the U. S. Bureau of Public Roads. Type *F* material in its loosest state may have a greater unit weight than any of the other types in their most dense states.

An interesting and significant fact is that the percentage corresponding to the mean size is not now an arbitrary constant quantity, but varies in a characteristic fashion with the type of grading curve, and, in reality, represents a skew factor. In Types *A*, *B*, and *C* the percentage may vary from about 45 to 55, and the median approximately coincides with the geometric mean. Since Types *E* and D_E are skewed to the fines, the percentage corresponding to the mean is considerably greater than 50, usually from about 55 to 65. In contrast, the percentage for Types *F* and D_F is considerably less than 50, usually from 35 to 45.

In an attempt to describe the grading curve by the slope of the curve or any part of it, there has been a confusion of two separate and distinctly independent ideas—the shape of the curve and the range of particle sizes—which cannot be expressed by any single factor. With degree of fineness defined by a geometric mean size or size factor, and the shape of the curve defined by the type, the size characteristics are finally defined simply in terms of the range of particle sizes, with no reference to slope, as such. The designation of range to take in the entire grading curve may be expressed conveniently as the ratio of the 95% size to the 5% size, or by the number of size factor units (intervals of log 2) between these two extreme sizes. For practical purposes the lower limit of the designation is taken at 0.001 mm and all materials finer are considered as colloidal materials.

The range of particle size also has a most important affect on density. For the same type of grading curve the greatest density is found in the material having the greatest range of particle sizes, and the least dense is always the narrow range Type *A* material.

On these bases it seems logical to define the size characteristics of soil in terms of the three independent factors, which not only have statistical but also physical significance in the grading-density relations,[11] and to define the soil fractions or soil separates in terms of a log 2 series, which is a continuation of the Tyler sieves.

A. J. WEINIG,[12] ESQ. (by letter).—The comparison of mechanical analyses and nomenclature of soils offered in this paper is particularly valuable in view of the many different systems included, and Mr. Campbell's proposed plans would seem to be a logical, general outcome of all these classifications.

In the matter of diameter-grade designation, a suggestion is made that if the type of distribution curve be represented by a letter, an instant mental picture of the soil type would be had. Thus, for example, if (C) represents convex; (K), concave; (S), S-type *n*-curve; and (L), linear, then the diameter-grade designation, of the samples given in the paper, for example, would be:

Sample:	Diameter-grade designation
(*a*)	D-0.0038–G-1.9 C
(*c*)	D-0.081 –G-1.0 S
(*e*)	D-1.45 –G-3.3 K

CARL H. KADIE, JR.,[13] JUN. AM. SOC. C. E. (by letter).—The author has developed a method of tabulating, in a simple form, a mass of information regarding the nature of the particle-size distribution of a soil sample. With the increasing use of soil classification and soil tests in the investigations of building foundations, earth dams, highway sub-grades, and erosion control, a need has been felt for a simple method of recording pertinent data on soil profiles and maps. Mr. Campbell's grade line, with the deviation therefrom, and the use

of the mean diameter, provides a means of supplying all the necessary information regarding the particle-size distribution and eliminates the ambiguous and difficult-to-read symbols generally used in such soil maps and profiles. The symbolic representation of soil classifications, when appearing on drawings which have been reduced in scale, is generally unintelligible. The writer believes that the method of grade lines is a remedy for the aforementioned difficulty, but to be useful it must be standardized. It would seem of little importance which sizes are chosen to correspond to the numbers, 1 through 5, but it is important that all data recorded by this method use the same system.

The need for standardization has been felt by many who have had occasion to read the reports from various engineering offices and Government bureaus. For example, it is of no importance whether the smallest particle size is found to the right or to the left of the mechanical analysis curve. Both conventions will be found in regular use. Probably more curves showing mechanical analyses of soils have been plotted with the small sizes at the left of the sheet, whereas concrete sands and aggregate are generally reversed. There are a great many exceptions to this, however. Although it is a small point, the standardization of this convention, regardless of the use made of the curve or of the material, seems highly desirable.

The writer does not agree that any material benefit may be derived from the proposed change in the limits of sizes in the various soil classifications. Since clay cannot be defined by size alone, the division between clay and silt must be of an arbitrary nature. Division by assigning a larger size to the upper limit of clay would save time in sedimentation analyses in reaching this point. The time, however, required to reach a particular size decreases with an increase in temperature or specific gravity. Each investigator can readily determine how much time he is justified in spending on the sedimentation analyses.

The United States Bureau of Chemistry and Soils has adopted size limits for each classification of soil. These limits have come into wide use, and in view of the fact that no soil class can be entirely identified by size alone, it seems desirable to adopt these limits as a standard.

The transfer of tabular data on soil separates to a mechanical analysis graph sheet for reproducing its curve, can be facilitated by the simple method shown in Fig. 3. The screens used to accomplish this separation are designated by number and a line is drawn on the graph sheet at the position of the size of their openings. The intermediate lines facilitate the determination of mean size and "grade line deviation." The "grade numbers" are those suggested by Mr. Campbell, and the soil classifications are those of the Bureau of Chemistry and Soils.

CARLTON S. PROCTOR,[14] M. AM. SOC. C. E. (by letter).—A timely subject is treated in a refreshingly lucid style in this paper. Mr. Campbell is to be complimented for an excellent contribution to a subject on which there is general engineering agreement as to its immediate importance; because, certainly, an engineering reference to a particular type of soil should be subjected to a uniform general interpretation and such is not now the case.

---

[14] Cons. Engr. (Moran, Proctor & Freeman), New York, N. Y.

The existing confusion in soil classification standards is largely a confusion in terminology, and a standard classification is to be expected only after the establishment of a standard terminology. The first step in this direction should be agreement as to the number of classifications to apply to each soil group.

Mr. Campbell proposes three classes of sand, whereas the U. S. Bureau of Chemistry and Soils includes four, and the classification listed in Fig. 1 as the "Tyler sieve" group gives five sand classes. A Tyler sieve classification was proposed by William P. Kimball, Assoc. M. Am. Soc. C. E., in 1936, based on the result of a practical experiment.[15] Professor Kimball submitted a series of bottled soil samples of Tyler sieve grain sizes to various experienced foundation engineers and found a close agreement in classification, in terms of silts, very fine, fine, medium, coarse, and very coarse sands, etc. Because the five grades of sand were invariably used and because the variations in classification occurred at the margins of silt to very fine sand, and sand to fine gravel, a Tyler sieve classification was proposed. A similar sub-division of sands was presented by T. A. Middlebrooks,[16] Assoc. M. Am. Soc. C. E., which covered essentially the same grain size ranges for each of the five sub-divisions. This classification was reported as having been used at the Fort Peck Dam, in Montana. The five-group sand classification confirms a wealth of experience of practicing foundation engineers in that for most reports received from the field, five classifications of sand are used. Therefore, the single criticism that can be made of Mr. Campbell's paper lies in his use of only three sand classifications and in the fact that the abscissa scale of Fig. 1 does not lend itself to four or five sub-divisions.

The soil classification that will be ultimately accepted as standard must be equally practicable of application in both field and laboratory and must follow the terminology familiar to, and accepted by, the contractor who will be guided by the engineer's plans and specifications. The scale proposed meets this condition except for sand, but the fact that Tyler concrete sieves are normally found in the ready equipment of engineers, architects, and contractors should not be overlooked in any consideration of a standard soil classification.

The importance of agreement in terminology of soil classifications lies in the practical consideration that most soil classifications are, and will probably continue to be, made as a result of experienced visual examination only, occasionally correlated by trial mechanical analysis to a preferred classification. Mechanical analysis of all, or nearly all, the samples in a large exploration project is too time-consuming and expensive for many operations.

The paper, as a whole, is highly commendable. The proposed method of recording and tabulating mean diameter, grade line deviation, and grade is ingenious and may well prove of real practical value. This is a logical development from the work of the late Allen Hazen, M. Am. Soc. C. E., in the field of filter sands.

[15] *Proceedings,* International Conference on Soil Mechanics and Foundation Eng., Harvard Univ., Cambridge, Mass., June, 1936, Vol. 1, pp. 302 to 305, inclusive.

[16] *Loc. cit.,* p. 145.

T. T. KNAPPEN,[17] M. AM. SOC. C. E. (by letter).—Grain-size distribution graphs give the engineer or technician a picture that is useful in suggesting, in a general manner, what the properties of a soil may be. The author has indicated a possible method of classifying grain-size curves for statistical purposes. Presumably, such classification might prove to be useful in co-ordinating physical properties with grain-size distribution. The author remarks that the grain-size curve is frequently an indication of type—that is, residual, alluvial, or æolian—and that it may be an indication of maturity. Otherwise, he does not suggest much use for his method of representing grain-size curves numerically. Possibly he can make the value of this method of classification more apparent.

In the past the writer has considered various methods, including several similar to that suggested by the author, for statistical comparison of the properties of soils, but abandoned them as useless. The engineer is interested in many properties of soils in their natural and remoulded states. Some of these properties are: Permeability; cohesion; internal friction; consolidation characteristics; structure; porosity, or void ratio; water content; chemical composition; specific gravity; etc. So many factors other than grain-size distribution are vital in predicting the behavior of a soil under certain conditions, that one wonders if any useful purpose can be served by the proposed method of classification. Its value must be less than the grain-size curve itself since it is only an approximate method of describing such a curve. To illustrate, the 50% size gives little if any indication of permeability, and even the 10% and 20% sizes may be of little use for this purpose. Unless there are more values than are apparent, it is the writer's belief that the introduction of such a method of classification would be only one more confusing factor in an already "muddled" field.

With his tabulation of the nomenclature used for various soil separates, the author illustrates the confusion now present in this field. He suggests still another method of classifying the separates. Arthur Casagrande, Assoc. M. Am. Soc. C. E., once suggested to the writer that these various efforts to apply well known soil names to these fractions were not only idle but also harmful. Remembering this remark the writer consulted a dictionary to see what these words meant to the authorities on language. Clay is defined[18] as,

> "A widely distributed earth, plastic and tenacious when moist and hardening when baked, consisting of pure kaolin or, more commonly, of a mixture of kaolin with more or less finely eroded material, chiefly quartz, feldspar, and mica. * * * Dry clay consists essentially of a compound of alumina, silica, and the elements of water. When it is subjected to a baking heat water is formed and passes off as steam and a material quite different from the original clay is left behind. It is very hard, and its powder, mixed with water, is not plastic. * * *"

Silt is defined as: "(*a*) Mud or fine earth suspended in running or standing water; (*b*) a deposit of such mud or fine earth." Sand is "a loose material consisting of small but easily distinguishable grains (most commonly of quartz), resulting from the disintegration of rocks. * * *"

---

[17] Engr. Mgr., Parsons, Klapp, Brinkerhoff & Douglas, New York, N. Y.

[18] Webster's New International Dictionary, G. & C. Merriam Co., 1930.

It might be best to forget the various attempts to apply these names to soil fractions and retain them as a common language for the engineer and layman. Are not such terms as "blow sand," "sticky clay," "soft silt," "loess," "gumbo," "coarse sand," "hard-pan," "boulder clay," etc., more descriptive for conveying to the engineer or layman the general properties of a soil than "D 0.022-G 3.9-Grade line deviation + 0.021"?

JACOB FELD,[19] M. AM. SOC. C. E. (by letter).—Separation of soil particles by means of square mesh screens is the oldest method of analysis for the purpose of classification. The author's proposed standardization of sizes to match grades covering the usual soil fraction names is complete and should be adopted. However, it must be carefully noted that the separation by screens does not distinguish between particles of different shapes. It is perfectly possible to have identical gradation curves, both for sizes and for percentages in each grade, for two very dissimilar soils. The differences in physical action of large grains, above the grade of fine sand, of different shapes can be disregarded. For smaller grains, ratio of surface area to mass becomes an important factor, because of the importance of surface tension and other cohesive forces in small-grained soils.

The effect of shape can best be pictured by the following tabulation of grains, all of which will be retained on a square-mesh screen with a width of opening slightly smaller than unity:

(1) A cube with unit side, has a volume of one, surface area of 6, and a ratio of surface to volume of 6.

(2) The cube split into halves by a plane parallel to, and midway between, two opposite faces; each grain has a volume of 0.5, a surface area of 4, and a ratio of surface to volume of 8.

(3) The cube split into halves by a plane, through two opposite edges; each grain has a volume of 0.5, a surface area of 4.41, and a ratio of surface to volume of 8.8.

(4) The cube split into three equal parts by two planes parallel to opposite faces; each grain has a volume of $\frac{1}{3}$, a surface area of 3.33, and a ratio of surface to volume of 10.

(5) The cube split into three equal parts by planes joining one corner with two edges meeting at the opposite corner (forming pyramids with a square base, two normal and two oblique faces); each grain has a volume of $\frac{1}{3}$, a surface area of 4.83, and a ratio of surface to volume of 14.5, almost 2.5 times that of the cube.

The process can be continued indefinitely, but the general picture shows why sand and clay or basically cubical and flat grains act so differently. When particles are in the silt and clay grades, shape is at least equal in importance with size.

HOWARD F. PECKWORTH,[20] M. AM. SOC. C. E. (by letter).—The concentration of graphical representation of grain-sized distribution into a recognized standard, as presented by Mr. Campbell, is an excellent proposal. If experience shows that his proposed system meets with general approval an effort would be made to secure its adoption as a standard.

---

[19] Cons. Engr., New York, N. Y.

[20] Civ. Engr., Pacific Constructors, Inc., Redding, Calif.

As the author proposes in part to fix the definition of "sand," "silt," "clay," and "colloid" in relation to grain size, and as it is necessary to distinguish between the popular usage of these words and their uses in relation to grain size, it is unfortunate that the meanings of the words, "silt" and "clay," are sometimes in such sharp disagreement with their meanings as proposed and as used in the grain-size distribution charts.

An example of this disagreement was demonstrated by a very thin bituminous coal seam running below a borrow-pit which supplied material for a rolled-earth dam. When the steam shovel, digging into the borrow-pit, broke through into this entirely unsuitable coal seam it picked up fine-grained, broken, coal which, when examined with the earth, fell between the grain sizes, 0.0006 and 0.06 mm; and yet this coal could never be called clay or silt by any stretch of the imagination.

Another example is presented by fines, dust, and waste from a sandstone crushing operation being piled next to a borrow-pit to be used for earth for a rolled-earth dam. When wet it was sometimes difficult to distinguish between the material in the borrow-pit and the dust from the waste pile. Some of the material in the waste pile would fall between the sizes, 0.0006 and 0.06 mm, on the grain-size distribution chart; and yet it was 90% pure silica particles, which again could not be called clay or silt.

If this proposed classification is to be adopted as a standard, the writer would like to suggest that the names of the gradations be changed from "sand," "silt," "clay," and "colloid," to "sand," "fines," "superfines," and "colloid," or some similar wording that would not bring such a sharp disagreement between the popular dictionary usage of the words, "clay" and "silt," with materials actually dealt with in soil mechanics other than clay and silt which nevertheless fall in sizes between 0.0006 and 0.06 mm.

JOEL D. JUSTIN,[21] M. AM. SOC. C. E. (by letter).—The author presents an interesting method of classifying soils. The semi-log scale, shown in Fig. 1, is in quite general use for plotting the results of mechanical analyses. Some technicians, however, plot with the small sizes at the left and the larger sizes at the right as the author has done in this case, whereas others plot with the large sizes at the left and the small sizes at the right. This seems like a small matter, but when one becomes familiar with the meaning of curves plotted in a certain manner and another technician appears, who insists on doing it differently, it takes some time before the curves mean very much.

There would seem to be no sound reason why the semi-log scale and its ratio for plotting results of mechanical analyses, as well as the direction of plotting, should not promptly be standardized. The writer does not care which way it is done as long as every one does it the same way.

The author proposes a soil classification based on two factors: (1) The mean grain size, the size than which 50% of the material by weight is smaller;

---

[21] Cons. Engr., Philadelphia, Pa.

and (2) a gradation factor based on the slope of the curve as more specifically defined by the author.

Such a method of classification would have its advantages, because a soil for which the mechanical analysis curve had a certain slope and a certain "mean grain size" would have fairly uniform physical properties common to other soils falling into the author's same classification.

The writer doubts, however, that the classification proposed by the author would have any practical advantage over the Kendorco classification and particularly over the modified Kendorco[22] classification as utilized by the U. S. Army Engineers of the Providence, R. I., District, and elsewhere.

In addition to any system of classification, such as the Kendorco, or the one advocated by the author, it is desirable to use a very general classification so that names, such as clay, silt, sand, and gravel, may be applied to soils with particle sizes that fall between certain limits. The so-called M. I. T. classification is satisfactory for this purpose.

The Kendorco classification has been used by the engineers of the Metropolitan District Water Supply Commission of Massachusetts and also in modified form by the U. S. Army Engineers of the Providence, R. I., District. Under this plan soils are classified by numbers. Even numbers indicate soils of relatively uniform grading, and odd numbers represent soils of relatively variable grading. Coarse soils are represented by the lower numbers and fine soils by the higher numbers. Thus, 2 in the modified Kendorco classification represents a uniform coarse, to medium, sand and 12 a uniform clay.

Synthetic samples representing the different classes (from 1 to 13) of soils may be made up. With a little experience one can, quite successfully, determine by visual inspection into what classification a given soil will probably fall. As soils falling into any given classification have quite uniform physical characteristics, and permeabilities are known within reasonable ranges in advance of tests on the actual samples, the idea has definite practical advantages.

The writer considers the modified Kendorco classification to be one of even greater practical usefulness to the engineer who must deal with soil as an engineering material, but who is not himself a soils technician. He hopes that some one of the engineers who have developed this method of classification to its present degree of usefulness will embrace the opportunity afforded by this discussion to describe it more fully.

L. B. Olmstead,[23] Esq. (by letter).—In the mechanical analysis of soil materials texture is expressed as percentages of several size classes. Numerous attempts have been made to increase the usefulness of these data by varying the size limits so that some simple mathematical relationship may exist between the diameters, areas, or volumes of the particles in the different classes. Others have attempted to increase the usefulness of existing data by various forms of curve plotting. Mr. Campbell has attempted both.

---

[22] "Permeability Determinations, Quabbin Dams," by Stanley M. Dore, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 102 (1937), pp. 682–711.

[23] Physicist, Div. of Soil Chemistry and Physics Research, Bureau of Chemistry and Soils, U. S. Dept. of Agriculture, Washington, D. C.

In addition to semi-logarithmic plotting of size limits against summation percentages, Mr. Campbell has picked out three points on the graph, presumably at such positions as he believes will usually furnish the best criteria of the shape and position of the curve. These points are called diameter-grade designation and grade-line deviation. Whether this contribution by the author succeeds in increasing the application of the mechanical analysis data will depend upon the use that will be made of it. Thus far, little use has been found in the laboratory of the U. S. Bureau of Chemistry and Soils, for derived data, or for graphical representations of mechanical analysis data. This is due in part, no doubt, to the fact that the chemical nature of the finer soil material, as well as the size distribution, affects the physical properties.

In attempting to draw conclusions from mechanical analysis data, it is necessary to take account of the validity of the data. Determinations made by the hydrometer and the pipette methods may not check, and sieves used in different laboratories for the same size limit may differ by more than 50% in area of mesh opening.

In his plan for size classification, Mr. Campbell proposes to adopt the limits, but not always the same grade names, used by the International Society of Soil Science for materials between 2 microns and 2 mm. He extends the range at each end of the scale, and subdivides each class once. Since, in this classification, the integers, 2 and 6, recur alternately, the ratios between class limits are 3 and $3\frac{1}{3}$, alternately applied. There are two other rhythms holding fast to the International size limits that might be considered if their practicality is ignored. One involves the ratios of 4 and 2.5, alternately applied. The class limits would be 0.2, 0.8, 2, 8, 20, 80, * * * microns. For most soils the separation at 8 microns is quite likely to give a more even division of the silt class than when the separation is made at 6 microns. Since the logarithms of 2 and 8 are 0.301 and 0.903, respectively, the mantissa differences are almost exactly 0.60 and 0.40, a circumstance that facilitates semi-logarithmic plotting. This plan is open to the same objection as that proposed by Mr. Campbell. It provides too many classes of the small grains and apparently too few of the large ones.

The other and more flexible system would retain the decimal classes of 2, 20, 200 and 2 000 microns, of the International System, and extend it at both ends of the scale, as Mr. Campbell proposes. Then, in regions where the number of size classes are inadequate for the needs of a particular laboratory, additional optional classes might be inserted, based upon the ratio of $\sqrt{10}$ between limits. If further separations should be required, the ratio $\sqrt[3]{10}$ or $\sqrt[4]{10}$ could be used, depending upon the number of sub-divisions needed.

This classification possesses a rhythm, which the mathematical mind appears so emphatically to demand, and makes a flexible provision for a sufficient number of size classes; but is it workable? There are no means of separating clastic materials strictly according to size. About all that can be done is arbitrarily to define equivalent diameters in terms of settling velocities and sieve specifications. If screening values are to yield equivalent sizes close enough to satisfy this classification, special screens, no doubt, will have to be provided. Even if the necessary special sieves might possibly be obtained, the selection of a classification which requires them is open to serious objection.

The writer suggests modifying this plan, in so far as it is necessary, in order to use standard or other accurate and easily obtainable screen materials. Sieves having screening values nearest the nominal sizes of the extended International Classification would be adopted and always used in the region where they apply. Highway engineers probably would omit the smaller sized groups and agronomists the larger ones. In addition, supplementary intermediate classes, utilizing standard screens, should be set up for use when more size classes are needed.

If conventional size designations are desired for the sieved material, they must be defined arbitrarily in terms of mesh openings, because the screening values of clastic materials varies with the shape factor. The present lack of accepted sieve specifications partly nullifies the benefits to be derived from the International Classification. In the smaller sized classes the relation of particle size to settling velocity permits sub-divisions of the material at almost any point. However, there is no fixed relation between settling velocity or particle size and the readings at stated time intervals of the soil hydrometers in common use. These hydrometers were originally calibrated for one particle size distribution, and their design is such that they cannot detect some unusual distributions no matter how many class limits are provided.

The fact that many institutions would not adopt a standard size classification of soil materials at this time is no reason why such a standard should not be set up and made available for all who are free to use it. Conditions may arise that permit laboratories to make gradual changes from the classification in use to a standard system. Much work and many years were required for the adoption of a classification by the International Society of Soil Science, and that classification should be used if possible as the basis of an amplified system.

The size limit of 2 microns appears to have been well chosen by the International Society. Accurate determinations cannot easily be made upon all kinds of soil materials below this limit, with the methods of dispersion and analysis now available. It is difficult to make satisfactory determinations even at this point upon some lateritic soils. In the U. S. Bureau of Chemistry and Soils the upper size limit of extracted colloids is not far from 0.2 micron, but the separation is seldom carried to completion. The upper limit for clay is now set at 2 microns, the material between 2 and 50 microns being classed as silt. An additional pipette sample is now taken for a 20-micron class limit, and a sieve separation is made at 0.2 mm, so that the results of analysis can be expressed in either the Bureau, or the International, Classification.

T. A. MIDDLEBROOKS,[24] ASSOC. M. AM. SOC. C. E. (by letter).—With all due respect to the author for his conscientious attempt to obtain uniformity in soil classification, it is believed that more could be done by withdrawing a number of classifications now in use, rather than recommending new ones to confuse the field further. Little can be gained by additional soil classificationsthat vary only slightly from standard accepted classifications. The classification offered by the author does not vary in any important features from the most widely used classification of the U. S. Bureau of Chemistry and Soils. Therefore, why change?

---

[24] Senior Engr., Office, Chf. of Engrs., Washington, D. C.

Grain-size dimensions in the silt and sand ranges are arbitrarily set and have no particular significance as to the soil characteristic. Whether the division between sand and silt is set at 0.05 mm or 0.06 mm is of no consequence. Engineers merely need time to become familiar with the classification agreed upon. On the other hand, the division between silt and clay is of great importance and it cannot be set satisfactorily on any particular grain size, but must be determined by mineralogical examination for the different types of clays encountered. Rock flour, which is finely ground rock mineral, may have a large percentage of grains within the clay range of grain sizes, but it will not have the characteristics of a clay mineral. The writer has found montmorillonite clays in which the division between silt and clay is approximately 0.005 mm and bedilite clay in which this division is approximately 0.002 mm; therefore, it is apparent that no definite limit can be set for clay.

Experience of the writer in various sections of the United States has shown that either the Massachusetts Institute of Technology, or the U. S. Bureau of Chemistry and Soils, classification is applicable for all types of soil provided the division between silt and clay is determined by mineralogical examination.

FRANK E. FAHLQUIST,[25] ASSOC. M. AM. SOC. C. E., AND WALDO I. KENERSON,[26] ESQ. (by letter).—A new method for graphically presenting the grain-size distribution of a soil is proposed by the author. He also submits a soil classification based on the mean grain size and gradation of soil particles. Acceptable standards for describing the grain-size distribution of soils are needed, and the author should be commended for presenting his ideas to the profession. The use of such expressions as uniform coarse sand or uniform fine sand conveys definite impressions of particular types of uniformly textured soil. However, the use of such expressions as sandy silt, silty sand, clayey silt, silty gravel, clayey loam, etc., conveys an inadequate conception of non-uniformly graded materials. Such terms are often interchanged and incorrectly used by engineers. This results in vagueness and considerable confusion.

The Bureau of Chemistry and Soils, U. S. Department of Agriculture, has devised a classification that has been in general use for many years. More recently, the so-called Massachusetts Institute of Technology (MIT) soil classification has been used increasingly among engineers and soil technicians. Both these classifications are included in Fig. 1 of the paper. The writers prefer the MIT classification because it is easier to remember and is more logically constructed in that successive decrease in arbitrary grain-size limits follows a definite pattern. However, neither the MIT nor the Bureau of Soils classifications are adequate for describing non-uniformly graded materials correctly. Furthermore, in analyzing fine-textured sediments, such as silts or clays, there is difficulty in recognizing the limiting sizes of each type of material. Soil scientists do not agree where the line should be drawn in separating colloids from the coarser fractions. Notwithstanding this fact, there appears to be no reason why arbitrary limits, such as are shown in the MIT classification, should not be used. The writers believe that use of the terms, "clay" or "fine silt," for instance, should be based not only on a grain-size analysis, but what is much more important from an engineering viewpoint, on the behavior characteristics of the material.

---

[25] Geologist, War Dept. at Large, U. S. Engr. Office, Providence, R. I.

[26] Chf., Soils Testing Laboratory, U. S. Engr. Office, Providence, R. I.

The author proposes to classify soils according to a mean diameter size (grain-size diameter at 50% ordinate) and five arbitrary grade lines as shown in Fig. 1. This is essentially an improved adaptation of the soil constants, "effective size" and "uniformity coefficient," introduced by the late Allen Hazen, M. Am. Soc. C. E. These new constants partly fulfill a long desired improvement growing out of appreciation by engineers of the inadequacy of Hazen's coefficients to classify soils properly.

A soil classification based on grain size only, however, is not sufficient. Engineers who have investigated the finer grained sediments have long recognized this point. Charles Terzaghi, M. Am. Soc. C. E., has stated:[27]

> "The properties that determine the behavior of the soil in the foundation pit directly are not the uniformity, nor the mineralogical composition, nor the water content. They are:
>
> "(1) The volume change produced by an increase of the pressure acting on the soil; * * *.
> "(2) The permeability of the soil; * * *.
> "(3) The cohesion or the shearing resistance of the soil under zero load; * * *."

The extent to which these properties are affected by the mineral and water content and natural structure must be determined in the soils laboratory before final classification is made.[28] In addition, a soil classification to be of practical use in the field must be adaptable to reasonably accurate classification of natural sedimentary deposits.

The Providence (R. I.), District, U. S. Engineers, has developed a soil classification which meets the requirements imposed by conditions in the field and by the behavior characteristics of the sediments. During the two years, 1936-1937, this idea has been fully tested and found reliable. More than 5 000 mechanical analyses performed in the Soils Laboratory have proved its adequacy both as to gradation and size limitation of the individual classes. It is based, but with important modifications, upon the Kendorco classification described by Stanley M. Dore, M. Am. Soc. C. E.[29] Rigidly standardized descriptive terms are used in the Providence classification as follows:

Class	Description of Material
1	Clean Gravel: Contains little coarse to medium sand.
2	Uniform Coarse to Medium Sand: Contains little gravel and fine sand.
3	Variable—Graded from Gravel to Medium Sand: Contains little fine sand.
4	Uniform Medium to Fine Sand: Contains little coarse sand and coarse silt.

---

[27] "The Science of Foundations—Its Present and Future," by Charles Terzaghi, *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 296.

[28] *Loc. cit.*, p. 297.

[29] "Permeability Determinations, Quabbin Dam," by Stanley M. Dore, *Transactions*, Am. Soc. C. E., Vol. 102 (1937), pp. 682–711.

Class	Description of Material
5	Variable—Graded from Gravel to Fine Sand: Contains little coarse silt.
6	Uniform Fine Sand to Coarse Silt: Contains little medium sand and medium silt.
7	Variable—Graded from Gravel to Coarse Silt: Contains little medium silt.
8	Uniform Coarse to Medium Silt: Contains little fine sand and fine silt.
9	Variable—Graded from Gravel to Medium Silt: Contains little fine silt.
10	Uniform Medium to Fine Silt: Contains little coarse silt and coarse clay. Possesses behavior characteristics of silt.
10C	Uniform Medium Silt to Coarse Clay: Contains little coarse silt and medium clay. Possesses behavior characteristics of clay.
11	Variable—Graded from Gravel or Coarse Sand to Fine Silt: Contains little coarse clay.
12	Uniform Fine Silt to Medium Clay: Contains little medium silt and fine clay (colloids). Possesses behavior characteristics of silt.
12C	Uniform Clay: Contains little silt. Possesses behavior characteristics of clay.
13	Variable—Graded from Coarse Sand to Clay: Contains little fine clay (colloids). Possesses behavior characteristics of silt.
13C	Variable Clay: Graded from sand to fine clay (colloids). Possesses behavior characteristics of clay.

Soils are divided into thirteen general classes. Distinctions between soil classes are based upon grain-size limits as shown graphically in Fig. 4. An important feature to be noted in this diagram is the flexibility allowed for the limiting diameters of fine silt and coarse clay. Either of these materials is allowed to range between 0.006 mm and 0.0006 mm. This flexibility is introduced by the writers in recognition of the fact that natural depositions of fine-textured sediments, such as glacial silts (rock flour), behave differently from clays despite similarity of grain-size distribution. It is interesting to note that this same flexibility is recognized by the Society's Committees on Road Materials, as shown by the author in Fig. 1.

Grain-size limits of the even numbered classes have been chosen arbitrarily so that the particle diameters at the 90% and 10% ordinates conform to the limiting sizes as recognized in the MIT classification. Investigations in the laboratory have disclosed that grain-size curves of variable depositions vary over a wider range in their upper parts as compared to their lower parts when attempts are made to conform to this classification. Therefore, the idealized and limiting curves for Classes 3, 5, 7, 9, 11, and 13 are discontinued at the 50% ordinate. Heavy full lines indicate idealized depositions, whereas broken lines indicate limiting boundaries within which classified depositions may vary.

Sediments which do not conform to either of the two principal idealized slopes can be easily classified by this system. For instance, a sediment can be classified as Class 7–5. This designation means that the upper part of the curve lies

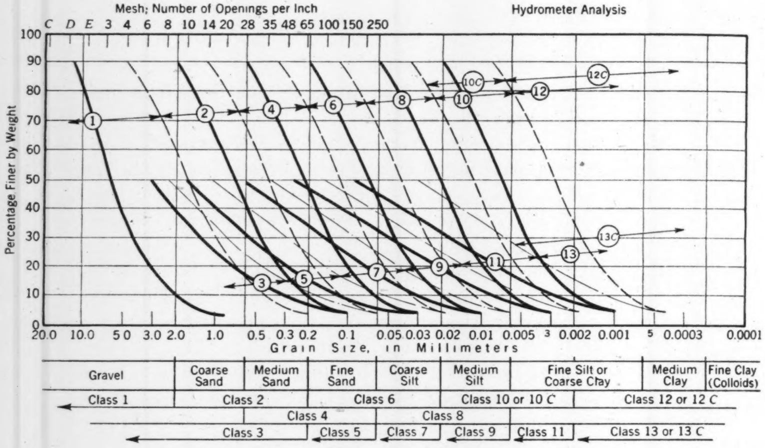

FIG. 4.—DIAGRAM SHOWING LIMIT OF SOIL CLASSES

within the Class 7 range and the lower part within the Class 5 range. Likewise, a Class 5–7 material indicates an extremely variable soil in which the upper part of the curve lies within the Class 5 range and the lower part within the

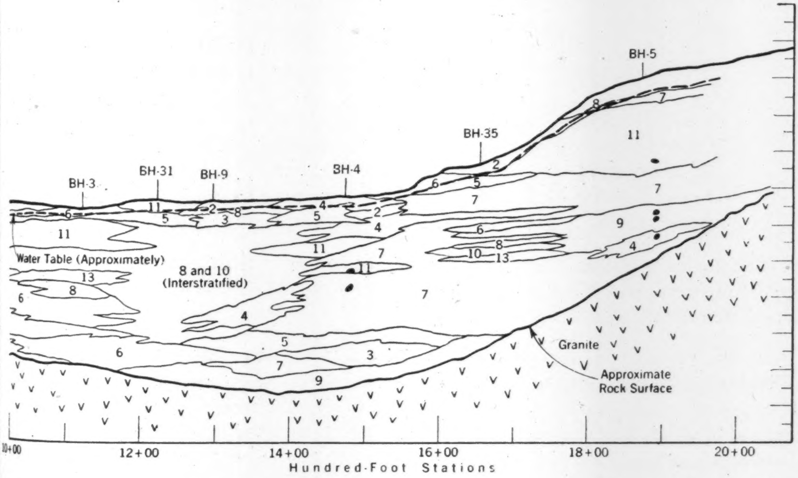
FIG. 5.—PROVIDENCE CLASSIFICATION

Class 7 range. This same procedure is applied to variations in gradations of uniformly textured soils. Thus, a Class 6–4 or Class 4–6 is recognized.

There is surprising conformity between the author's grade lines as shown in Fig. 1 and the several possible gradations recognized in the Providence classification: The author's Grade 1 conforms very closely to the slope of the idealized curves for Classes 1, 2, 4, 6, 8, and 10; Grade 2 conforms to the slope of variations in the foregoing sediments recognized as Classes 2–4, 4–6, 6–8, 8–10, 10–12; Grade 3 conforms to the Providence Classes 5–3, 7–5, 9–7, 11–9, 13–11; Grade 4 conforms to Classes 3, 5, 7, 9, and 11; and Grade 5 conforms to Classes 3–5, 5–7, 7–9, 9–11, and 11–13.

It is to be noted that the Providence classification does not rely upon certain soil constants, such as the 50% mean diameter in Mr. Campbell's classification or the grade lines, as obtained from the 20% and 80% sizes. Instead it utilizes the entire mechanical analysis curve. This is accomplished with the aid of a transparent sheet of celluloid on which is inked a full set of classification curves similar to those in Fig. 4. The master plat is placed and oriented over an unclassified grain-size curve. The class range into which this curve falls is immediately apparent and is recorded directly on the curve sheet. This method makes for rapidity and accuracy.

The behavior of fine-grained sediments particularly general Classes 10, 12, and 13 is markedly different when considered from a regional standpoint. Thus, in the glaciated New England area, fine-grained sediments derived by glacial abrasion and occurring in glacial lake deposits are found, by tests, to be angular in shape of grain, capable of being consolidated rapidly, slightly compressible (depending partly upon the mica content), and possessing a high angle of internal friction. These sediments can be properly designated as silts



APPLIED TO GEOLOGIC SECTION

or rock flours. In contrast, alluvial sediments of similar fineness from the Mississippi Valley have decidedly different properties. These sediments are often composed of flat and scale-like clay particles, together with coarser fractions derived from rock decay. They consolidate slowly, are highly compressible, and possess a low angle of internal friction. It is readily seen that to classify these materials, as Class 10, for example, without further qualification would lead to misunderstanding on many important and critical properties. In such cases the Providence classification provides for referring to the former as Class 10, and to the latter as Class 10C, the letter C indicating behavior characteristics of clay.

The author's statements as to the geologic significance of the mechanical analysis curve are valuable. In the past, the geologic aspect of soils has been too little appreciated by engineers and soil technicians. The ease with which soils classified under the Providence System can be indicated in geologic sections is shown in Fig. 5. The character of the material in a formation and the mode of occurrence are generally reliable criteria as to the geological history of that formation. Certain sedimentary types are more prominently developed in one section of the country than in another. For example, glacial deposits are prominently developed in the northern part of the United States and Canada. Loess deposits, probably of wind-blown origin, occur throughout a large part of the Mississippi Valley, particularly in Nebraska, Wisconsin, and Arkansas. Soils in the South and Southwest are largely of residual origin. In river valleys throughout the United States there are large accumulations of alluvial deposits of both fine and coarse texture. A few examples of the accumulations in certain recognized geologic formations are:

Geology	Classes
Alluvial deposits (coarse-textured)	1, 3, 5, 7, 9, 2, 4
Alluvial deposits (fine-textured)	4, 6, 8, 10, 10C, 12, 12C, 11, 13, 13C
Glacial deposits—till	9, 11, 13, sometimes Class 7
Glacial deposits—outwash	1, 3, 5, 7, 2, 4, 6
Glacial lake deposits	6, 8, 10, 10C, 12, 12C
Aeolian (wind-blown) deposits	4, 6, 8
Loess deposits	Chiefly Class 8
Residual soils	3, 5, 7, 9, 11, 13, 13C

The author's classification has considerable merit. His paper comes at an opportune time, and it is felt that it will result in considerable clarification as to acceptable definitions of soil separates.

E. W. Lane,[30] M. Am. Soc. C. E. (by letter).—In this brief but very enlightening paper, Mr. Campbell has discussed three principal points: (1) The use of semi-logarithmic paper for plotting mechanical analyses; (2) a method of indicating the variability of the size graduation; and (3) a suggested division of soils into classes according to the size of the particles of which they are composed, with class names. In the following paragraphs the writer will discuss each of these three points in turn.

---

[30] Associate Director in Chg., Iowa Inst. of Hydr. Research, Univ. of Iowa, Iowa City, Iowa.

The use of the semi-logarithmic type of gradation curves advocated by the author has much to commend it and, particularly in the field of earth-dam material, it is much superior to any other method of graphical representation of particle sizes with which the writer is acquainted. Another method extensively used, particularly by geologists, is the so-called histogram, which is simply a bar graph, the length of each bar of which represents the percentage of the total material between two sizes. The number of bars depends on the number of fractions into which the sample was divided. Another type is a summation curve similar to that advocated by Mr. Campbell, but for which a Cartesian scale of co-ordinates is used for the grain diameter in place of a logarithmic one.

The semi-logarithmic plotting of a summation curve is much superior to either of these methods. The disadvantages of the histogram method are that it is not standardized since the widths of the bars are all the same, but each bar may represent any size range selected by the investigator. The shape of the histogram also depends upon the number of fractions into which the sample is divided. It is not possible to determine the percentage of the material smaller or greater than any specified size, except such sizes as the limits of a particular fraction, and then only by a process of adding the lengths of the bars between that point and one end of the diagram. In the semi-logarithmic plotting, the curve will be practically the same regardless of what limits are used for the various fractions, and it is possible to determine the percentage greater or less than any specified size and also to determine the median size or size for which 50% is greater and 50% smaller. This size forms a convenient single value to express the size of the material.

In the form of summation curves using the Cartesian co-ordinates for the grain diameter, unless the chart is very long, the smaller sizes are difficult to read and plot accurately. Very fine sizes particularly come so close to the zero size line that it is very difficult, if not impossible, to read them. In the semi-logarithmic plotting, the scale of the smaller size is enlarged, and it is possible to read accurately down to the finest particle used. For purposes of comparison, it is possible, using the semi-logarithmic paper, to plot on the same sheet, using the same co-ordinates, the size distributions of a number of samples with much less confusion than is possible using the other methods.

In the plotting of sizes of material moved by flowing water there is frequently considerable uniformity of particle size and the curves often take the shape of Mr. Campbell's Sample (*c*). They frequently have a distinct S form, showing that the greater part of the material is of nearly uniform size, but that a small part has a considerable size range larger than the main body and that another small part has likewise a considerable range smaller than the principal part. As these small fractions may prove to have a considerable bearing on the transportation of the material, it is desirable that the method of graphical representation used indicate their proportions accurately. A system of co-ordinates which would expand the extremities of the "per cent larger" scale would aid in this desirable end. The writer is experimenting on the development of such a form of paper.

Mr. Campbell's comparison of the various classifications—clay, silt, sand, etc.—serves to emphasize the lack of agreement among the workers in this field. Mr. W. W. Rubey[31] has mentioned several others, including those in Table 2, Columns (1) (2), and (3), each of which has had considerable use. Still another classification is that used by L. G. Straub, Assoc. M. Am. Soc. C. E. It is the same as that of Mr. C. K. Wentworth except that it divides silt into four classes. Mr. Campbell's classification has much to recommend it, but the writer fears that no classification recommended by an individual, regardless of how eminent he may be, will be universally accepted. It seems probable that the advantages of any reasonable classification, if widely accepted, would more than offset any disadvantages that might occur in case the standard was not the best possible one, and, therefore, considerable advantage would result from the general adoption of a single standard. That classification should be adopted which seemed to be most generally acceptable to all groups, and if no agreement can be reached with other groups, it is suggested that civil engineers at least adopt one standard. Any one who had definite opinions on the superiority of another classification would still be free to use the grouping of his choice. Perhaps an agreement on certain features of the method of plotting could also be standardized, such as whether the size range should increase or decrease toward the right, and whether the percentage smaller

[31] ***Professional Paper 165A,*** **U. S. Geological Survey, p. 23.**

than or larger than a given size should be used for the ascending scale of ordinates.

The standard of gradation or uniformity suggested by Mr. Campbell, the writer believes to be a very good one. Although it has a purely empirical basis, so far as known no classification on a more rational basis has been suggested. It has the great advantage of being easy to obtain. No such standard will be widely used which for each sample requires the expenditure of considerable time for its determination. The writer has long recognized the desirability of some easily determined coefficient of variability for convenience in expressing in numerals, roughly, the composition of samples of granular material. He believes that the two numbers, median size (50% of the weight composed of larger particles and 50% of smaller particles) and the Campbell variability coefficient, together make possible a fair representation of the size and gradation of a granular material.

It is believed, however, that it would be possible to improve the proposed gradation coefficient. Mathematically, the value of this coefficient is 10/6 of the logarithm (Base 10) of the ratio of the "80% smaller" size to the "20% smaller" size. To use 6/6, the logarithm of this ratio, instead of 10/6, would have several advantages. The coefficient would then have a simpler physical meaning, which is always an advantage, especially in defining it. Knowing the 80% and 20% sizes, it would be possible to determine approximately the coefficient by mental calculations, and an accurate computation could be readily made with a slide-rule, requiring one less operation than the form proposed. Graphically, it would be the number of cycles of the semi-logarithmic scale between the 20% smaller and 20% larger point. This distance could be measured directly without drawing the slope line on the graph. The value of this proposed revised coefficient in every case would be 0.6 of that of the one proposed by Mr. Campbell. Some thought should also be given to the possibility that the use of, say, the 15% and 85% points on the 10% and 90% might be preferable to the 20% and 80% points.

F. J. SANGER,[32] ASSOC. M. AM. SOC. C. E. (by letter).—It is a well established fact that the only way to describe the grading of a soil is graphically, and the best chart is probably the one commonly used, having the log scale at the bottom for grain sizes. The terminology used in describing grains of particular grain sizes cannot be justified. To take existing, well understood terms describing natural soils and to use them for more precise meanings very near, but very different from, their previous meanings, is unscientific and misleading. The exact divisions are artificial and hence can never be standardized to agree with all points of view. Why not, then, discard these confusing divisions? If it really is necessary to subdivide the horizontal scale according to present practice, other terms should be used, and probably a numbering system is best. The grain-size distribution of a particular natural soil, as specified in the chart used by the U. S. Bureau of Public Roads, can better be shown by an area bounded by two curves, inside which a soil of the particular class must lie. Engineers are not in the habit of defining structures and machines by lengthy descriptions;

---

[32] Head, Dept. of Eng. and Building, The Lester School and Henry Lester Inst. of Technical Education, Shanghai, China.

but rather by the use of drawings. Why not describe the grain-size distribution that way and not bother about printing percentages?

With regard to grain shape, is it not probable that the moisture and plasticity tests, as given in A. S. T. M. publications, take full account of the important effects?

This means that to describe a natural soil, a chart and some moisture and plasticity data are necessary—not a list of percentages, which are difficult to appreciate as they stand. Natural moisture content, specific weight of soil particles, and natural voids ratio from which density of the mass can be calculated, are also desirable, of course. The point is that the list of percentages should be superseded by the curve and that the existing terms for sub-divisions should be discontinued. The importance of the geologic history of the soil is now being appreciated and a description of the soil should include such a history, where it is known.

F. KNAPP,[33] ESQ. (by letter).—The proposal of the author to designate a particular soil by means of the grain size and the grade is most helpful and, in combination with Fig. 1, serves to give an immediate idea as to the type of the soil. Furthermore, this proposal makes generic designations, such as clay, sand, etc., superfluous. The writer would suggest that a more complete diagram of the several hundred samples mentioned by the author be included in the closing discussion.

The graphical representation of analyses of soils and their definitions by the mean grain size and grade should be helpful in permitting a more logical interpretation of a hydraulic problem, namely, the permissible maximum velocity in earth canals in order to prevent erosion. Although other factors still enter into the problem (such as the cross-section of the canal and the velocity distribution) it is clear that the properties of the soil are of outstanding importance.

Russian engineers[34] have published a table of permissible velocities in clayey soil, subdivided into four classes according to porosity. From the few indications given in regard to grain size, the writer plotted the distribution as proposed by the author. The product of mean grain size and grade multiplied by 10^3 may be plotted as abscissa, the velocities as ordinates, and the porosities as parameters. With some imagination it was found that a curve could be fitted to the various points, considering especially that the properties of soil in Nature do not change abruptly. Such a representation serves to indicate more clearly the inter-relation of the permissible velocity and the properties of the soil.

CHARLES H. LEE,[35] M. AM. SOC. C. E. (by letter).—Two objectives are definable in this paper: First, to standardize graphical representation of grain-size distribution; and second, to simplify and systematize the interpretation of such graphs. Both undertakings are opportune and it is to be hoped that the first, especially, can be carried through to an early definite conclusion. The second is more a matter of individual experience, technical background, and judgment, and cannot be reduced to set rules. The author's method of simplification is an interesting one.

[35] Cons. Hydr. Engr.; Chf. of Div., Water Supply and Sanitation, Dept. of Works, Golden Gate International Exposition, San Francisco, Calif.

As for a graphical standard, the writer agrees with the author in favoring the one with the ordinate as percentage by weight of total sample plotted to natural scale, and the abscissa as particle size, in millimeters, plotted to a logarithmic scale, with small sizes at the left and large sizes at the right. In plotting the results of standard sieve and hydrometer analyses, however, it is found more convenient to have every number from 1 to 9 in each log cycle represented by a vertical line, and, in addition, to have the half lines between 1 and 2 and the standard sieve size lines. The use of log 2 and log 6 or any other combination, although giving a more open diagram, is not convenient for plotting or for picking off end points of soil fractions.

A form of graphical diagram which the writer has developed by trial through the ten years, 1928–1938, is presented in Fig. 6. It includes five cycles ranging in size from 0.001 to 152.4 mm which covers all ordinary requirements. Its one limitation is exclusion of smaller clay sizes extending into the colloids.

Fig. 6 also includes tabular spaces for entering standard Tyler sieve percentages that are held, and size classification according to the U. S. Bureau of Chemistry and Soils. This form has been found to have a wide appeal because it is easily understood, both by those who are familiar with separation by standard Tyler sieves and by those who use the U. S. Bureau of Soils classification. It is the writer's observation that the vast majority of American engineers are familiar with one or the other of these classifications, and that the engineering use of other classifications is confined to a relatively few specialists in soil technology.

The classification favored by the writer for an engineering standard is that of the U. S. Bureau of Chemistry and Soils. The reasons for such choice are: (1) It is generally recognized and widely used both by engineers and by scientific research workers; (2) the fractions conform reasonably well with distinctive physical characteristics resulting from particle size; (3) it has proved reasonably satisfactory in general use; and (4) it can be readily taken from a graph plotted from the results of any sieve and hydrometer, pipette, or similar analysis which a great variety of established laboratories are equipped to make.

The author's generalization that immature soils have size-distribution curves that are concave upward and mature soils convex upward is not supported by inspection of such curves from broad geographic areas. Curves that are concave upward represent a material in which the larger sizes predominate, whereas those in which small sizes predominate have curves that are convex upward. If the original rock contains non-weathering grains of relatively large size, such as quarts or silica, the curve may be concave upward even if weathering has reached a stage of maturity. Such a condition exists in regions of granitic rocks such as granite, diorite, etc. Rocks of this type comprise large areas in all parts of the world and contribute non-weathering constituents to both residual and transported earth materials.

Alluvial materials may vary from the uniform grain-size type to the well-distributed type, depending upon the velocity conditions at the point of deposition. Alluvial débris deposited by swiftly flowing streams at a point of

Fig. 6

grade change have size-distribution curves that are straight and sloping, or concave upward, rather than vertical. Flowing water is an excellent sorting agent only if the velocity is uniform, such as in streams traversing broad valleys or shore currents in lakes or in the ocean; but in streams that drain steep topography, the velocity changes rapidly, affording little opportunity for sorting.

The mean grain size, as defined by the author, is entirely arithmetical and has no physical meaning. Mean grain size, as a weighted geometric mean, can be determined readily from a size distribution diagram, and it is not a step in advance to adopt an arbitrary definition. The attempt to express gradation by the slope of the line passing through the 20% and 80% points on the curve is equally arbitrary, and will lead to confusion rather than simplification. The entire curve must be taken into consideration in studying the size distribution characteristics of a material.

The nomenclature proposed by the author for designating these arbitrary values is too complicated to be remembered or readily grasped mentally, and is impractical for use. The proposed size classification with log-2 and log-6 division is also arbitrary and differs from those already in use. There are no compelling reasons advanced in its favor and its adoption would add to the confusion in an already over-confused field.

In classifying size-distribution graphs the writer gives consideration to physical characteristics more or less controlled by size distribution, such as porosity, permeability, and density. At one end of the scale are uniform grain-size materials, with high porosity and permeability, but low density. Such materials are sought after as sources of well water. At the other end are well-graded materials whose graphs follow closely a curve with an equation of the form:

$$p = \frac{(d)^n}{D} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which p = the proportion by weight passing a given screen or sieve opening; d = size of opening; D = maximum particle size; and n = an exponent ranging from 0.25 to 0.40. Such material has a low porosity and permeability, and high density, and is excellent for use in constructing earth embankments. An ideal group of five such curves with maximum sizes of particles equal to 0.6, 2.36, 8, 32, and 127 mm, percentages of clay equal to 30, 22, 13, 7, and 3, and values of n equal to 0.25, 0.25, 0.28, 0.30, and 0.33, are shown in Fig. 6.

Superimposed upon this sequence of grain-size distribution is the effect of size, which in fine silt and clay produces greater porosity than in coarser fractions, lower density, and far less permeability. In conjunction with water the fines also introduce the new characteristics of shrinkage and slow consolidation under load. The limiting curves of the group in Fig. 6 include the ranges of size distribution and of size, which experience has shown are satisfactory for construction of impervious sections of rolled-fill earth dams. It is to be noted that Curves *a* and *f* in Fig. 1 are both beyond the limiting curves of the group, and both were unsatisfactory for this type of construction.

Frank B. Campbell,[36] Assoc. M. Am. Soc. C. E. (by letter).—It is felt that the paper has been worth while if only for the interesting and valuable discussion that it has provoked. There appears to be a general desire that something should be done to bring order out of the multitude of systems in current use for the recording and the nomenclature of particle-size distribution in soils. The paper was not presented (as some one has suggested) to add another method to an already "muddled" field, but rather as a logical compromise of the two principal existing systems.

The paper presented four proposals or conceptions regarding the mechanical analyses of soils:

(1) A proposal for the standardization of the form of the mechanical analysis graph;

(2) A proposal for the standardization of the nomenclature of soil fractions based upon a compromise between the American, or Whitney, scheme and the German, or Atterberg, scheme;

(3) A method for expressing approximate distributions of particle sizes and the mean size for use on maps, cross-sections, or tabulations (this proposal is offered as a tool to be used only when found convenient for the sorting of a large number of mechanical analyses); and,

(4) A suggestion as to the interpretation of the mechanical analysis graph in terms of the history of the soil.

Standardization of the Graph.—It is indeed fortunate that the vertical ordinate of percentage by weight smaller than a given particle size, plotted with increasing magnitude upward, has found fairly common acceptance. This leaves, then, only the sense, vectorially speaking, of the horizontal ordinate or abscissa to be considered.

In closing, it should be emphasized that some engineers and scientists plot their abscissas with increasing magnitude to the right, whereas others plot them with increasing magnitude to the left. As Mr. Justin has so aptly expressed it, "This seems like a small matter, but when one becomes familiar with the meaning of curves plotted in a certain manner and another technician appears, who insists on doing it differently, it takes some time before the curves mean very much." Professor Burmister and Messrs. Fahlquist and Kenerson have shown graphs with increasing magnitude toward the left. Messrs. Kadie and Lee as well as the writer, have plotted grain size as abscissas with increasing magnitude toward the right.

For the purpose of this discussion the writer will define a positive sense of the abscissa as increasing magnitude toward the right and a negative sense as increasing magnitude toward the left. There may be a good reason for plotting with a negative sense but, unfortunately, no one has offered such reason. The writer feels that originally some one may have had the idea that the upper limit of particle sizes in soils is definite and that the lower limit is indefinite, due to the advancing technique of modern science, which may permit the measurement of smaller diameters in the future. There is probably a definite lower limit if sedimentation methods are to be used. Mr. R. C. Thoreen[37] has clearly defined the limitations of Stokes' law. It would appear then, that the limitation of practical methods of measuring small sizes would indicate plotting the smallest sizes at the left. Considering the fact that both Europeans and English speaking people read with a positive sense from left to right, it would seem more in agreement with their sense of direction if data were plotted with increasing magnitudes toward the right. Furthermore, even the layman is familiar with the classical "first quadrant" of plane geometry. There would probably be less mental confusion for the technician who plots with a negative sense, to change to a graph using a positive sense, than for the technician who has already employed a positive sense, to reverse his procedure. For this reason the writer is presenting a suggested standard form, shown in Fig. 7. It would be somewhat inconvenient for the engineer or scientist who only occasionally plots grain-sized distribution to use a negative sense, in that the semi-logarithmic paper usually available on the market is constructed with a positive sense. Although there is no zero to the logarithmic scale, the left-hand margin of the graph could be started at 0.002 mm, or 2 microns, for all practical purposes. It is fairly positive that sedimentation methods will not be used to determine diameters smaller than 0.6 micron. The expensive and tedious methods of microscopy may yield determinations smaller than the aforementioned limit, but this remains for scientists of the future to determine.

---

[36] Associate Engr., War Dept., U. S. Engrs. Office, Denison, Tex.

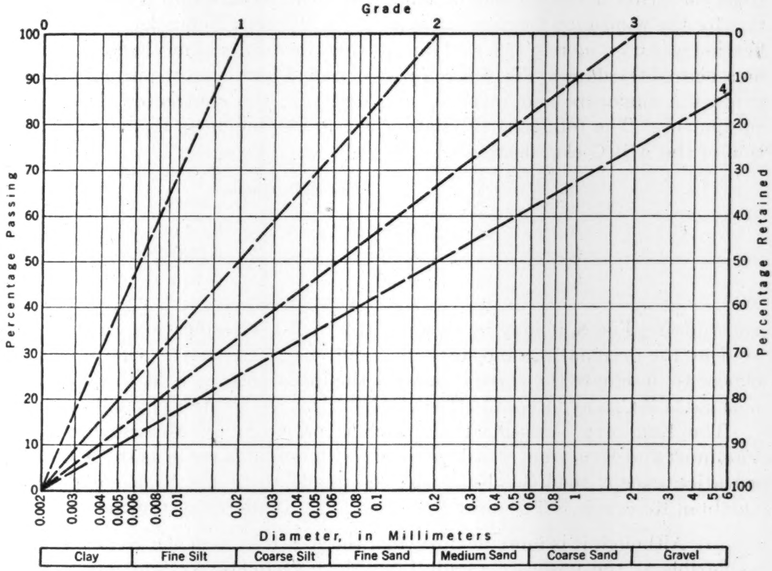

FIG. 7

Messrs. Kadie and Lee have called attention to the fact that Fig. 1 does not have an adequate number of abscissa lines for close plotting. Their contention is true; Fig. 1 was included for demonstration purposes only. The writer is accustomed to using graph paper similar to that shown by Mr. Kadie for purposes of making an accurate record of mechanical analysis data. The method of using heavy lines to correspond to sieve openings of the Tyler series has been found to be very convenient for the purpose of plotting the sieve-analysis data.

---

[37] "Comments on the Hydrometer Method of Mechanical Analysis," by R. C. Thoreen, *Public Roads*, Vol. 14, pp. 93–105.

Grade Line-Mean Diameter.—During the winter of 1934–1935 the Platte Valley Public Power and Irrigation District employed a number of inspectors in its Soils Laboratory under the direction of the writer. With adequate assistance it was possible to make about 700 mechanical analyses on borrow-pit material as well as other tests, such as Proctor compaction and percolation tests, before the ground thawed and construction was begun in the spring. At that time, the writer devised a classification which can be called an A B C classification for the wind-blown or aeolian material in Western Nebraska. This classification was used merely as a tool for plotting the results of mechanical analyses on a plan of the dam. Fig. 8 was a part of one of four borrow-pit maps used to guide the engineers and inspectors in directing the contractor's excavating equipment. The following tabulation is a grade-line-mean-diameter designation of the A B C classification:

Local classification	Proposed Designation: Grade line	Mean diameter
A	0.60	0.041
B	0.85	0.080
C	1.60	0.145

By studying Fig. 8, it may be seen that the A B C classification was very convenient for designating fine, medium, and coarse material. One might also choose to designate the three classes by the initial letters, F M C. The designations, A B C, may be confused with soil horizon designations by soil surveyors.

The Kendorca[37] classification which is preferred by Messrs. Justin, and Fahlquist and Kenerson, was developed for the same purpose as the A B C classification except that the Kendorca was made to fit the local conditions at Quabbin Reservoir. The disadvantages of the Kendorca system are as follows:

(*a*) Although it is more flexible than the A B C system the Kendorca is not as flexible as the proposed Grade-Line-Mean-Diameter system; nor is it any more precise; and,

(*b*) The system is incomplete in that odd numbers do not indicate the existence of any material between the 100% and 50% lines.

Regardless of the two foregoing disadvantages the writer can readily understand that the Kendorca classification may have been very valuable as a tool for the materials problem which the originators had to solve. However, it is believed that if one becomes accustomed to working and speaking with the terms of the 20–80 Grade-Line-Mean-Diameter system it will be found more flexible than establishing some fixed line on a mechanical analysis graph. The modifications proposed by Professor Lane are well worth considering. The writer believes that the use of 10% and 90% intersection points for establishing a grade line would be workable for soils that have the curve symmetrical about the 50% axis. The disadvantage of using 10% and 90% would be the large deviation introduced at 50% mean diameter when the distribution curve has either exaggerated convexity or concavity. Professor Lane's suggestion of using 6/6 of the ratio of the interval rather than 10/6 would be merely another mathematical designation of the grain-sized distribution. It would have the advantage, as he suggests, of enabling the computer to make a hurried mental calculation of the grade instead of resorting to graphical methods. Professor Weinig's method of adding symbols to the diameter grade designation to indicate convexity, concavity, S-type, and linear curve, is certainly an excellent suggestion. It would probably add much to the value of the data on a plan or cross-section if the soil presented these four different types of particle-size distribution.

FIG. 8.—CLASSIFICATION OF BORROW-PIT MATERIAL, SUTHERLAND RESERVOIR DAM

Nomenclature of Soil Fraction.—There appears to be an attitude, as expressed by Messrs. Knapp, Knappen, and Sanger, that the generic names of soil fractions on separates should be discarded entirely. However strongly one may feel toward discarding the English words—colloids, clay, silt, sand, and gravel—

they have grown to have a definite meaning of magnitude through the widespread use of mechanical analyses. The general difficulty appears to arise in attempting to reconcile the German *schlamm*, *schluff*, *mo*, and *sande*, to the conception of English-speaking people. If it should be agreed by an international commission on soil nomenclature to establish names for soil separates, with due consideration to the generic meaning of both German and English terms, it may be desirable to compromise by designating the fractions by the letters of the Roman alphabet which is acceptable in both languages. For instance, one could call colloids the *a* fraction, clay the *b* fraction, silt the *c* fraction, sand the *d* fraction, and gravel the *e* fraction. There would then remain only the problem of standardizing the size limits. Another alternative would be to use the Greek alphabet in the manner that radio-active rays are designated. On the other hand, the American and English lexicographers would probably appreciate precise definitions of generic words which have heretofore been used very loosely by scientists, engineers, and laymen alike.

Mr. Middlebrooks raises a question as to the reason for changing from the Bureau of Chemistry and Soils classification. The writer believes that the reason for changing is that a large group of engineers and scientists have already begun to swing toward the more logical scheme of Atterberg by setting the division lines at recurring logarithmic cycles in multiples of 2. As stated by Professor Lane, Atterberg's[38] original classification called for the upper limit of clay to be drawn at 2 microns. The same limits established by Atterberg have been followed by the International Classification.

Few engineers and scientists in America have become accustomed to the International, or the Atterberg, designation until recently. In the meantime the Americans have used the U. S. Bureau of Chemistry and Soils Classification for many years. The writer is indebted to Mr. Olmstead[39] for a brief history of the Bureau of Chemistry and Soils Classification:

> "The earliest publication I have seen that gives the Bureau grain size classification is the report of Professor Milton Whitney in the Fourth Annual Report of the Maryland State Agricultural Experiment Station, 1891, pages 249–296. *Bulletin 4* of the Division of Agricultural Soils, published in 1896, states that it is the practise of the Division to separate mineral soils into eight grades, according to diameter of grains, and gives the same limits as does the Maryland station report. No author's name appears on this *bulletin*. Osborne employs some of the same size limits in his mechanical analyses of soils published in the Connecticut Agricultural Experiment Annual Reports for 1886–7. I have seen no discussion of the origin of the Bureau classification but I believe it was devised by Professor Whitney some time before he came to the Department of Agriculture as the first chief of the Bureau of Soils."

The Bureau of Soils classification, therefore, is distinctly American, having its origin sometime during the latter part of the Nineteenth Century. Many English-speaking scientists have become accustomed to it. On the other hand, there is the more rational classification as far as limits or divisions of the soil fractions, which apparently originates with Atterberg.

---

[38] "Die rationelle Klassifikation der Sande und Kiese," von A. Atterberg, *Chemische Zeitung*, Jahrgang 29, 1905, pp. 195–198.

[39] Personal letter to the writer from L. B. Olmstead, Soil Physicist, U. S. Bureau of Soils, Washington, D. C., dated October 12, 1938.

As mentioned in Mr. Olmstead's discussion, the engineers would probably prefer to have more divisions in the coarse range whereas the agronomist would prefer more divisions in the fine range. In the proposed classification, an attempt has been made to establish limits for fine, medium, and coarse sand, which roughly approximates that of the Whitney scheme except log 2 − log 6 has been used for the limits. More divisions than the old Whitney system have been made available in the range of clay and silt. For these reasons it should be usable by both engineers and agronomists.

A comparison of the advantages and disadvantages of the several systems can be outlined briefly as follows:

I.—Atterberg or International Classification:
  (*A*) Advantages.—
    (1) The class limits are set at 2, 20, 200, and 2 000 microns making a good arrangement for semi-logarithmic plotting.
  (*B*) Disadvantages.—
    (1) There is some difficulty of applying the German terminology to the American concepts of size classification.
    (2) There are too few divisions in the coarser range.
    (3) The upper limits of clay at 2 microns is too high for efficient laboratory determination where a large number of samples are involved. The laboratory time required for the Bouyoucos hydrometer is approximately 6 hr.

II.—Whitney or Bureau of Chemistry and Soils Classification:
  (*A*) Advantages.—
    (1) There is a widespread familiarity with this system among American professional men and perhaps also laymen.
    (2) The numerous divisions in the larger materials make it convenient for macroscopic examination of soils in the field by engineers and soil surveyors.
    (3) It establishes a very practical upper limit for clay whether the pipette or hydrometer method is used.
  (*B*) Disadvantages.—
    (1) The size limits of the class do not conform to evenly divided logarithmic spacings. Whitney's proposal was probably originated before the common use of semi-logarithmic plotting.
    (2) Too few divisions in the smaller size are included. This is a disadvantage to the agronomist principally, although others may soon be interested, with the advance of the study of soil mechanics.

III.—Massachusetts Institute of Technology Classification:
  (*A*) Advantages.—
    (1) Sand is divided into three commonly accepted classifications; namely, fine, medium, and coarse.
    (2) Sand classes roughly approximate those of the Bureau of Chemistry and Soils.

(*B*) Disadvantages.—
  (1) There are three classes, each, of silt and clay. The three classes of clay have as yet proved to be of little use to the engineer.
  (2) This has the same disadvantage as the International in that the upper limit of clay is depressed to 2 microns instead of at the proximity of 5 microns according to the Whitney system.

IV.—Proposed or Log 2 − Log 6 Classification:
  (*A*) Advantages.—
    (1) This is a classification to agree roughly with the Whitney system which has grown to be the American conception of size classification.
    (2) It is a division of soil fraction based upon log 2 − log 6 which is patterned after the Atterberg system.
    (3) An upper limit of clay is set at 6 microns instead of 2 or 5 microns. Such a definition allows clay to be determined in less than 1 hr with a Bouyoucos hydrometer as compared with more than 6 hr for the Atterberg definition. For the investigation of any particular borrow-pit, where the number of samples to be examined is known, this advantage can be evaluated in terms of dollars and cents. With the more cumbersome pipette method, a shorter distance of settlement can be used, but accuracy is sacrificed. The Bouyoucos hydrometer method is usually conceded to be a more efficient method, although the pipette is desired by some technicians.
  (*B*) Disadvantages.—
    (1) The writer feels that a distinct difficulty exists in that a compromise is suggested between the two schools of thought; namely, those who are experienced with the Whitney system and those who have become accustomed in recent years to the Atterberg system with its modifications.

History of Soils.—Professor Burmister and Mr. Sanger obviously concur with the writer that the mechanical analysis is an indication of the history of the soil.

Mr. Lee dissents with a statement that the premise given by the writer may not be true in the case of resistant quartz or silica. Although quartz may be more resistant to weather than other minerals, it has been observed that even such hard crystals are vulnerable to breakage by freezing and thawing of interstitial water. Even diurnal variation of temperature in the warmer latitudes may cause the disintegration of quartz. This is widely evidenced in the Piedmont region of Southeastern United States. However, Mr. Lee's argument should be considered because the writer's suggestion as to maturity and immaturity of soils is probably more applicable to the podzols of the northern latitudes.

Messrs. Feld and Sanger have mentioned the shape of particles. This fact is important in that, the determination of mechanical analyses by a combination of sieving and sedimentation methods does not take the shape into account. Some one has well defined a diameter determined by sedimentation methods as the "equivalent diameter of a perfect sphere falling in a viscous fluid." As a general rule the presence of angular and plate-shaped particles increase the stability of embankments, although more effort may be required for the mechanical compaction of such soils. The angular particles may require more fines to fill the voids and produce imperviousness. It has been the writer's practise to carry a pocket microscope giving magnification to approximately 60 diameters, when working in the field. Thus, the shape of particles of approximately 20 microns may be inspected visibly. This diameter is the lower limit of coarse silt on the proposed classification.

General Consideration.—In closing, the writer suggests that individuals, interested societies, governmental agencies, and educational institutions should work together in drafting a standard form of mechanical analysis graph, which, in effect, is a language used by many professional men. Consider the confusion if one were to attempt to write the words "mechanical analyses" backward as follows: "sesylana lacinahcem."

ECONOMIC PIPE SIZES FOR WATER DISTRIBUTION SYSTEMS

BY THOMAS R. CAMP,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. CLINTON L. BOGERT AND J. M. M. GREIG, CHARLES M. MOWER, JR., A. C. MICHAEL, ELLWOOD H. ALDRICH, M. H. KLEGERMAN, F. KNAPP, AND THOMAS R. CAMP.

SYNOPSIS

The method for determining the economic size of a single pipe line is well established and has been used for some time. In the past some efforts have been directed toward the extension of this method to a water distribution system, but the procedure to be used was not sufficiently developed for practical application. Had the method been available, it would have been of little use in design because of the difficulty of determining the distribution of flow in a pipe network. Practical methods for analyzing the distribution of flow in pipe networks have been published by the writer elsewhere[2] as well as by Hardy Cross,[3] M. Am. Soc. C. E., and James J. Doland,[4] M. Am. Soc. C. E. In order to apply one of these methods to the actual design of a distribution system, it becomes desirable to give further thought to the economic sizes of pipes. It is the purpose of this paper to develop methods for determining the proper sizes of pipes in distribution systems for best economy.

INTRODUCTION

The general method for determining the economic size of pipe is to express the total cost of the system as a function of the pipe sizes and find the pipe sizes that will make this cost a minimum. The total cost consists of the fixed cost, capital plus depreciation, and the operating cost which is the cost of pumping. Two general types of systems are encountered in practice, namely,

those with pumped supplies, and gravity systems in which there is no cost of pumping. Mr. George W. Tuttle[5] has shown that in some gravity systems the available head is so low that it is more economical to pump. In other words, a gravity system may not be the most economical type for a given case. Nevertheless, once a gravity system is decided upon, the cost of pumping ceases to be a part of the total cost.

Most modern American distribution systems consist largely of cast-iron pipe. The cost of mains in terms of the pipe diameter is presented hereafter only for such pipe. If some of the mains are constructed of other materials, or are built as tunnels, the economic sizes may be derived by methods similar to those presented, provided the costs of such mains can be stated in terms of their sizes. In the following development it is assumed that the cost of pumping, which necessarily includes capital cost of station, equipment, and operator's wages as well as power cost, is directly proportional to the head and to the discharge. It is also assumed that the cost of elevated storage will not be influenced by changes in pipe sizes and that this cost, therefore, need not be considered.

In the design of a distribution system, the location of the mains is usually determined by the location of the consumers. Preparatory to the determination of pipe sizes, the system is divided into districts, and the domestic and fire drafts are estimated for each district. The system is then "skeletonized" to show only the larger mains which play important parts in the delivery of water to each critical point in the system. The domestic and fire loads for each district are assumed to be concentrated at some point or points on the skeleton system. In simplifying the system, the errors introduced by neglect of small pipes must be examined and corrections made if they are found to be too large. Moreover, the location of a fire load in one district may require a modification of the skeleton system used for the fire load in another district.

By the trial-and-error method of, alternately, selecting pipe sizes for the skeleton system and computing corresponding pressure drops, a set of pipe sizes may be found which produces the desired residual pressures at each critical point in the system. The set of pipe sizes thus selected will be only one set of an infinite number each of which may produce the desired residual pressures. In order to obtain the most economical system, it will be necessary to examine the relation of the sizes for best economy as the trial-and-error process is in progress.

Notation.—The symbols used in this paper are defined where they first appear and are assembled for reference in the Appendix.

COST IN TERMS OF PIPE DIAMETER

The first cost of laying cast-iron pipe, in cents per linear foot, based upon cost data cited by the late Dabney H. Maury,[6, 7] M. Am. Soc. C. E., may be expressed as follows:

$$C_c = B\,D = \left[(0.06 + 0.02\,d)\,C_w + 0.19\,C_l + 0.007\,C_y\right] D \ldots\ldots (1)$$

---

[5] "The Economic Velocity of Transmission of Water Through Pipes," by George W. Tuttle, *Engineering Record*, September 7, 1895, p. 258.

[6] *Engineering News-Record*, May 11, 1922, p. 779.

[7] "Water Supply Engineering," by H. E. Babbitt and J. J. Doland, Members, Am. Soc. C. E., McGraw-Hill, 1931, p. 424.

in which,

$$B = (0.06 + 0.02\,d)\,C_w + 0.19\,C_l + 0.007\,C_y \ldots\ldots\ldots\ldots (2)$$

d = the depth of the trench, in feet; C_w = the wage rate for common labor, in cents per hour; C_l = the cost of lead in cents per pound; C_y = the cost of yarn, in cents per pound; and, D = the diameter of the pipe, in inches.

The costs given by Mr. Maury apply to trenches in ordinary soil without pumping, sheeting, rock, or other unpredictable costs. One joint was assumed for every 11 ft of pipe. As Mr. Maury's data made no allowance for contractor's profit, engineering, insurance, and interest during construction, the cost given by Equation (1) has been made approximately 20% greater than Mr. Maury's cost, in order to cover these items. The unpredictable costs may be omitted safely from the equation inasmuch as they will not be affected much by the pipe size. The cost of hydrant installations is also independent of the size of the main and may be omitted from the equation.

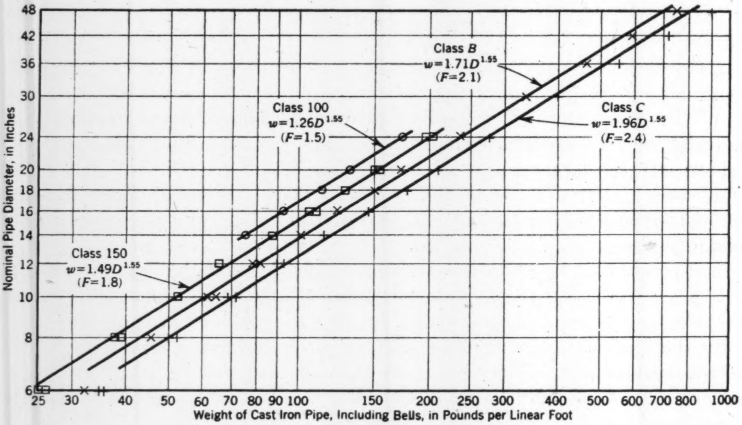

FIG. 1

A study of the weights of standard bell-and-spigot cast-iron pipe (Fig. 1) indicates that the weight, in pounds per linear foot, varies as the 1.55 power of the diameter with errors not exceeding 10% for any single pipe size. A study of the weights of fittings, which are frequently paid for by the pound, indicates that these weights may be assumed to vary as $D^{1.55}$. A study of valve costs shows that they also may be assumed to vary as $D^{1.55}$ for practical purposes. A study of the cost of linings, as given by Mr. E. T. Killam,[8] indicates that either cement or bitumastic enamel lining will cost about 7% of the cost of unlined cast-iron pipe. Therefore, the first cost of materials, including cast-iron pipe, valves, fittings, and pipe lining, in cents per linear foot of pipe, may be expressed by the following empirical equation:

$$C_m = F\,C_f\,D^{1.55} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

---

[8] "Economic Significance of Pipe Linings," by E. T. Killam, *Water Works and Sewerage*, March, 1933, p. 73.

in which C_f = the cost of cast-iron pipe, in cents per pound, with freight allowed; and, F = a coefficient giving the cost of different types of pipe at the trench, including appurtenances and 20% allowed for contractor's profit, engineering, etc. Typical values of F are given in Table 1.

TABLE 1.—VALUES OF F, EQUATION (3)

Class	UNLINED PIPE		LINED PIPE (CEMENT OR BITUMASTIC ENAMEL)	
	Pipe only	Pipe with one valve, one tee, and one cross for each 500 ft	Pipe only	Pipe with one valve, one tee, and one cross for each 500 ft
100	1.50	2.05	1.65	2.20
150	1.80	2.35	1.95	2.50
B	2.10	2.65	2.25	2.80
C	2.40	2.95	2.55	3.10

The annual cost, in cents, of pumping, or of water power, is:

$$C_a = 236\, C_p\, Q\, h \qquad (4)$$

in which C_p = the cost, or the value, in cents, of raising 1 000 000 gal 1 ft; Q = the discharge, in cubic feet per second; and, h = the head, in feet. If h is the friction head for a single pipe, it may be expressed as a function of the slope of the hydraulic grade line and the pipe length. The slope may be expressed as a function of the pipe size by using any convenient formula for pipe friction. The value of the slope, S, from the Williams-Hazen formula is:

$$S = \left(\frac{1\,594}{\mathsf{C}}\right)^{1.85} \frac{q^{1.85}}{D^{4.87}} \qquad (5)$$

in which C = the Williams-Hazen coefficient; and q = the discharge through the pipe, in cubic feet per second.

GRAVITY SYSTEMS

A gravity system is defined as one in which the total head available for loss through pipes is fixed by the topography. Flow is by gravity from a distributing reservoir, the elevation of which has been fixed without regard to the economic size of pipes in the distribution system. In such a system the cost of pumping, if pumping is required, is fixed arbitrarily by the elevation of the distributing reservoir and, hence, is independent of the size of pipes in the distribution system.

The economic pipe sizes for a gravity system will be one set that utilizes all the available head in friction when delivering the peak flow to each critical point in the system. If the system consists of a single pipe line, as is the case of a gravity water supply line, the determination of the economic size is direct and simple. When there are several pipes in series, however, and the costs per foot differ, there are an infinite number of ways in which the total head may be distributed among the pipes. Only one of these ways will produce a minimum cost for the entire series.

Let the cost of a series of gravity pipe lines be:

$$C = c_1 + c_2 + c_3 + \cdots c_n = f_1(h_1) + f_2(h_2) + f_3(h_3) + \cdots f_n(h_n) \ldots \tag{6}$$

in which $c_1, c_2, c_3 \cdots c_n$ = the cost of Sections 1, 2, 3, $\cdots$ n; and, $f_1(h_1)$, $f_2(h_2)$, $f_3(h_3) \cdots f_n(h_n)$ = these costs expressed as functions of the head loss in each section. The cost of any two connecting pipes in the series may be made a minimum for any given total head for these two pipes by equating to zero the first derivative of this cost with respect to the head loss in either section, thus:

$$\frac{d(c_1 + c_2)}{dh_1} = f_1'(h_1) - f_2'(h_2) = 0 \ldots\ldots\ldots\ldots \tag{7}$$

since $dh_1 = -\,dh_2$. Hence, for minimum cost of the first two sections:

$$\frac{dc_1}{dh_1} = \frac{dc_2}{dh_2} \ldots\ldots\ldots\ldots \tag{8}$$

Since this is the condition of minimum cost for any given total head in the first two sections, it is also the condition of minimum cost for the total head consistent with minimum cost for the entire series. A similar relation exists for each two connecting pipes in the series. Therefore, for minimum cost of the entire series:

$$\frac{dc_1}{dh_1} = \frac{dc_2}{dh_2} = \frac{dc_3}{dh_3} = \cdots \frac{dc_n}{dh_n} \ldots\ldots\ldots\ldots \tag{9}$$

and,

$$h_1 + h_2 + h_3 + \cdots h_n = H \ldots\ldots\ldots\ldots \tag{10}$$

in which H = the total head available for loss in the series. A graphical solution of this problem for an aqueduct is given in an example by Messrs. Babbitt and Doland.[9] For cast-iron pipes in a gravity series, the cost is,

$$C = [B_1\,D_1 + F\,C_f\,D_1^{1.55}]\,l_1 + [B_2\,D_2 + F\,C_f\,D_2^{1.55}]\,l_2 + \cdots\cdots \tag{11}$$

in which l_1, l_2, etc., equal the lengths of Sections 1, 2, etc. From the Williams-Hazen formula,

$$D = 16.5\,\frac{q^{0.38}\,l^{0.205}}{\mathbf{C}^{0.38}\,h^{0.205}} \ldots\ldots\ldots\ldots \tag{12}$$

Substituting this value of D for each pipe size in Equation (11) and differentiating as in Equation (9), the following result is obtained:

$$3.38\,\frac{B_1\,q_1^{0.38}}{\mathbf{C}_1^{0.38}\,S_1^{1.205}} + 24.5\,F\,\frac{C_f\,q_1^{0.59}}{\mathbf{C}_1^{0.59}\,S_1^{1.318}} = 3.38\,\frac{B_2\,q_2^{0.38}}{\mathbf{C}_2^{0.38}\,S_2^{1.205}} + 24.5\,F\,\frac{C_f\,q_2^{0.59}}{\mathbf{C}_2^{0.59}\,S_2^{1.318}} \ldots\ldots\ldots\ldots \tag{13}$$

Equation (13) gives the relation between the slopes of the hydraulic grade lines of any two connecting pipes in a gravity series for best economy. It may be solved by trial and error, but the process is difficult and time-consuming.

---

[9] "Water Supply Engineering," by H. E. Babbitt and J. J. Doland, Members, Am. Soc. C. E., McGraw-Hill, 1931, p. 237.

By assuming that the exponent of the slope in every term of Equation (13) is 1.25 an approximate solution may be had, as follows:

$$\frac{S_1}{S_2} = \left[\frac{3.38 \dfrac{B_1 q_1^{0.38}}{C_1^{0.38}} + 24.5\, F \dfrac{C_f\, q_1^{0.59}}{C_1^{0.59}}}{3.38 \dfrac{B_2 q_2^{0.38}}{C_2^{0.38}} + 24.5\, F \dfrac{C_f\, q_2^{0.59}}{C_2^{0.59}}} \right]^{0.8} \quad \text{.............} (14)$$

Results obtained by means of Equation (14) will usually vary by not more than 2% from those obtained by Equation (13). In applying it to the design of a distribution system, every pipe series should be considered that delivers water to a critical point for the condition of peak flow to that point. For another loading condition (that is, with the fire load at another critical point) other pipe series will come into play. The main feeders, however, will be parts of series for several loading conditions. The economic sizes of these mains, as determined for the several loading conditions, will not be identical, and it will be necessary to select some standard pipe size which comes nearest to satisfying all the conditions.

CLASSIFICATION OF PUMPED SUPPLIES

A number of cases arise with pumped supplies which affect the manner of determining the economic pipe sizes. In all these cases, it will be assumed that the minimum head is fixed at the delivery end of the pipe or pipe series at the required residual value for peak flow. The pumping head over and above this static head is chargeable to pipe friction.

If the discharge is constant, this additional pumping head has only one value consistent with best economy for the system; and there is only one set of pipe sizes that will give the least total cost. A distribution reservoir may be inserted in this system without affecting the economic pipe sizes, provided its elevation does not disturb the hydraulic grade lines.

If the discharge is variable, the pumping head may be either fixed or variable, depending upon whether a distribution reservoir is provided near the pump station. Each case will entail a different set of economic pipe sizes, and both sets will differ from the economic sizes for constant discharge.

Case I.—Pumped Supply with Constant Discharge.—If the system consists of a single pipe line discharging only at the lower end, the total annual cost of pipe and pumping against friction per linear foot of pipe is:

$$C_{at} = B\, r\, D + F\, C_f\, r\, D^{1.55} + 236\, C_p \left(\frac{1\,594}{C} \right)^{1.85} \frac{q^{2.85}}{D^{4.87}} \quad \text{......} (15)$$

in which r = the annual rate of interest plus depreciation of the pipe. Differentiating this cost with respect to the diameter and equating the result to zero, the following relation is obtained:

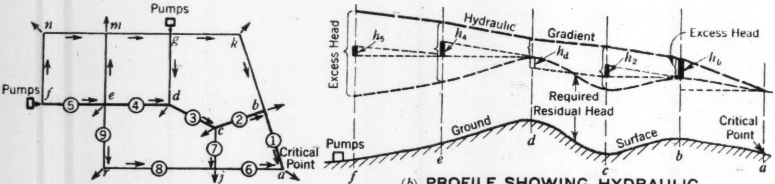
$$B\, r\, D^{5.87} + 1.55\, F\, C_f\, r\, D^{6.42} = 1\,150\, C_p \left(\frac{1\,594}{C} \right)^{1.85} q^{2.85} \quad \text{.....} (16)$$

Equation (16) may be solved by trial and error for the economic diameter of pipe. However, if the exponent of D in both terms is assumed to be 6.15, following the procedure of Babbitt and Doland,[10] the following approximate solution for the economic diameter is obtained:

$$D_{ec} = \frac{27.4}{\mathrm{C}^{0.30}} \left[\frac{C_p}{r\,(B + 1.55\,F\,C_f)} \right]^{0.163} q^{0.46} \ldots\ldots\ldots\ldots\ldots (17)$$

The coefficient in Equation (17) has been adjusted to 27.4 to compensate for the error introduced by changing the exponents. This formula gives values of the economic pipe diameter within 3% of those given by Equation (16).

If the system consists of a network of pipes with a number of take-offs, the pressure at only one take-off point may be made to correspond with the desired residual pressure. At each of the other take-off points there is an excess of pressure, and there is a power loss, therefore, corresponding to the draft from the system and this excess pressure. Some of the power loss at take-offs is due to the topography of the city and is not influenced by pipe sizes; but some of it is properly chargeable to pipes inasmuch as larger pipes down stream from a take-off point would reduce the excess pressure at the point.



(*a*) PLAN OF SYSTEM

(*b*) PROFILE SHOWING HYDRAULIC GRADIENT ALONG ONE ROUTE

FIG. 2.—ILLUSTRATING CASE I, PUMPED SUPPLY WITH CONSTANT DISCHARGE THROUGHOUT

In the simple network represented by Fig. 2(*a*) all the excess head at Point *b* is chargeable to Pipe 1. The part of the excess head at Points *c*, *e*, and *f*, corresponding to the lost head in Elements 2, 4, and 5, is chargeable, respectively, to those pipes. The excess head at Point *d* is due to Pipes 1 and 2; and the difference between the total head charged to these pipes and the excess at Point *d* is chargeable to Pipe 3. Since this value is negative in the example, the take-off power charge for Pipe 3 is a credit. To formulate a rule:

> (1) The head corresponding to the take-off power loss chargeable to any pipe is the head lost by friction in the pipe, or the difference between the excess head at the upper end of the pipe and the sum of the heads chargeable to the pipes down stream, whichever is the smaller.

The take-off power loss chargeable to Element 1, Fig. 2, is due to the draft from the system at Points *b* and *k*, and a part of the draft from Points *c*, *d*, *e*, *m*, and *n*. Since the loss due to the take-off at Point *c* is chargeable to Elements 6 and 7 as well as to Pipes 1 and 2, it is convenient to apportion the loss by distributing the draft at Point *c*, between the two routes. A similar distribution of the draft from other points should be made between the routes down stream from these points. To formulate a rule:

---

[10] "Water Supply Engineering," by H. E. Babbitt and J. J. Doland, Members, Am. Soc. C. E., McGraw-Hill, 1931, p. 425.

> (2) The discharge corresponding to the take-off power loss chargeable to any pipe is the sum of the drafts from the system at all points up stream from the pipe, a suitable apportionment of drafts being made between parallel routes.

For any pipe of a network through which water is pumped at a constant rate, the total annual cost, per linear foot of pipe, of pipe and power loss due to pipe friction and take-offs is given by:

$$C_{at} = B\,r\,D + F\,C_f\,r\,D^{1.55} + 236\,C_p\left(\frac{1\,594}{\mathrm{C}}\right)^{1.85}(q + m\,Q_t)\,\frac{q^{1.85}}{D^{4.87}}\,\ldots(18)$$

in which q = the discharge through the pipe, in cubic feet per second; Q_t = the total take-off discharge chargeable to the pipe, in cubic feet per second, estimated as described herein; and, m = the ratio of the take-off head to the head lost by friction in the pipe, the take-off head being estimated as described herein.

Following the procedure used in the derivation of Equation (17), the economic diameter of pipe for any element in a network through which water is pumped at a constant rate, is given by the following equation:

$$D_{ec} = \frac{27.4}{\mathrm{C}^{0.30}}\left[\frac{C_p\,(q + m\,Q_t)}{r\,(B + 1.55\,F\,C_f)}\right]^{0.163} q^{0.30}\,\ldots\ldots\ldots\ldots(19)$$

Case II.—Pumped Supply with Varying Demand and Varying Pumping Head; No Storage in System.—If throughout the design period, the discharge and head loss for any element vary such that q_a, q_b, q_c, etc. = the discharge for times, t_a, t_b, t_c, etc., and h_a, h_b, h_c, etc. = the corresponding friction heads, the average annual cost of the power loss is:

$$C_a = 236\,C_p\left[q_a\,h_a\frac{t_a}{t} + q_b\,h_b\frac{t_b}{t} + q_c\,h_c\frac{t_c}{t} + \cdots\right]$$

$$= 236\,C_p\,q\,h\left[\frac{q_a\,h_a}{q\,h}\frac{t_a}{t} + \frac{q_b\,h_b}{q\,h}\frac{t_b}{t} + \frac{q_c\,h_c}{q\,h}\frac{t_c}{t} + \cdots\right] = 236\,C_p\,A\,q\,h\,..(20)$$

in which q and h = the average discharge through the element and the corresponding head, respectively, over the design period; t = the design period; and,

$$A = \left[\frac{q_a\,h_a}{q\,h}\frac{t_a}{t} + \frac{q_b\,h_b}{q\,h}\frac{t_b}{t} + \cdots\right]\ldots\ldots\ldots\ldots\ldots(21)$$

Using the Williams-Hazen formula,

$$A = \left(\frac{q_a}{q}\right)^{2.85}\frac{t_a}{t} + \left(\frac{q_b}{q}\right)^{2.85}\frac{t_b}{t} + \left(\frac{q_c}{q}\right)^{2.85}\frac{t_c}{t} + \cdots\ldots\ldots\ldots(22)$$

For a particular case of a single pipe line with a 20-yr design period and with a constant pumping rate throughout any one day, the writer estimated a value of 2.1 for A. For the same pipe line designed to care for hourly fluctuations in demand. the value of A was estimated at 2.9.

The economic diameter of any pipe in a system through which water is pumped at a varying rate and against a varying head (Fig. 3) is given by the following equation:

$$D_{ec} = \frac{27.4}{\mathbf{C}^{0.30}} \left[\frac{C_p\, A\, (q + m\, Q_t)}{r\, (B + 1.55\, F\, C_f)} \right]^{0.163} q^{0.30} \ldots\ldots\ldots\ldots (23)$$

in which q = the average discharge through the pipe throughout the design period; and m and Q_t = values corresponding to q estimated as described for Equation (18).

FIG. 3.—PROFILE SHOWING HYDRAULIC GRADIENT ALONG ONE ROUTE, FOR CASE II, PUMPED SUPPLY WITH VARYING DEMAND AND VARYING PUMPING HEAD; PLAN OF SYSTEM SAME AS FIG. 2; NO STORAGE

The foregoing analysis is based upon the assumption that the flow is distributed throughout the system in the same ratios at all times. Fire flows are excluded since they account for a negligible part of the yearly pumping cost.

It is assumed in the foregoing derivations that for each discharge there is a corresponding friction loss for each pipe. This is not true throughout the design period for pipes in which the friction coefficients change with age. Since the economic diameter of a pipe varies inversely as $\mathbf{C}^{0.30}$, a reduction in the value of $\mathbf{C}$ during the design period as great as from 130 to 80, for example, will produce a variation in the economic diameter as computed from the foregoing equations of only 15 per cent. If the average value of $\mathbf{C}$ expected throughout the design period is used in the equations, the error in the computed economic pipe size will be small.

Case III.—Pumped Supply with Varying Demand and Constant Pumping Head; Elevated Storage at Pumps.—In this case (Fig. 4) the pumping head will be fixed by the peak flow through the system, including fire flow, and will be maintained constant by a distribution reservoir or elevated tank placed near the pumps at the elevation for best economy. The annual cost of pumping is not affected by the rate of pumping.

The power loss chargeable to each pipe for friction and take-offs is determined from the maximum friction head and from the average discharge over the design period. The elevation of the tank is established by the maximum friction head through the system.

FIG. 5.—ILLUSTRATING CASE IV, PUMPED SUPPLY WITH VARYING DEMAND AND VARYING PUMPING HEAD. ELEVATED STORAGE REMOTE FROM PUMPS

The economic diameter of any pipe in the system for a varying discharge and constant pumping head is given by the following equation:

$$D_{ec} = \frac{27.4}{\mathrm{C}^{0.30}} \left[\frac{C_p\,(q + m\,Q_t)}{r\,(B + 1.55\,F\,C_f)} \right]^{0.163} q_{\max}{}^{0.30} \ldots\ldots\ldots\ldots (24)$$

in which q = the average discharge in the pipe throughout the design period; and, $q_{\max}$ = the peak discharge, including fire flow, and other quantities are the same as for Equation (23).

Case IV.—Pumped Supply with Varying Demand and Varying Pumping Head; Elevated Storage Remote from Pumps.—In this case (Fig. 5) the elevation of the distributing reservoir will be determined by the maximum friction loss through the pipes delivering water from the reservoir to the critical point. This will occur with the maximum draft from the system, including a fire load at the critical point. Presumably, the pumps would be operating at their maximum capacity during a fire, as this practice would make for the greatest economy in the design of the system.

The variation in discharge for normal demand is not similar for all pipes in a system of this type. In some of the pipes, as in Pipe 4 of Fig. 5, the direction of flow reverses. For others, such as Pipes 1, 2, and 3, the flow is always in the same direction for normal demand. Although the pumping head varies, the manner of variation is controlled by both the rate of pumping and the demand, which do not vary similarly and are not equal. The increased cost of pumping due to variable head is chargeable to friction loss in the pipes between the pumps and the elevated storage, and is substantially independent of the pipes down stream from the elevated storage.

In so far as the manner of determining economic sizes is concerned, three types of pipes may be distinguished in a system of this class, as follows:

(1) Pipes down stream from the elevated storage on direct routes to the critical point, such as Pipe 2, Fig. 5. These pipes may be considered as falling in Case III, and their sizes may be determined by means of Equation (24).

(2) Pipes on direct routes between pumps and elevated storage, such as Pipe 5, Fig. 5, may be considered as falling in Case II and their sizes determined by Equation (23). The values of A and q can be approximated only very roughly since they are influenced by both demand and pumping rates.

(3) Pipes that are similar in nature to both Types 1 and 2, such as Pipe 4, Fig. 5, which is down stream from the storage for the fire load at Point a and is en route from pumps to storage for minimum demand. Both Equations (23) and (24) may be used for estimating the economic size of pipes of this type. Equation (23) should be given greater weight for Pipe 4 since the influence of this pipe on the fluctuations of the pumping head is greater than its influence upon the established elevation of the storage. About equal weight should probably be given to both equations for finding the size of Pipe 8.

In the application of Equation (23) to the determination of the size of pipes in which there is a reversal of flow, such as in Pipe 4, the effect of the reversal is to increase the range of fluctuation of the pumping head. Since negative friction losses correspond with savings in pumping head, however, they should be credited to the pipe by using negative values of the corresponding terms in Equation (22) for the solution of A, which value will thus be small for pipes in which there is a reversal of flow for normal demands.

ECONOMIC VELOCITY

The discussion of economic pipe sizes in terms of economic velocity has been purposely avoided in this paper. Notwithstanding the fact that many engineers have become accustomed to thinking of the economics of pipes in terms of velocities, the practice is valid only in very special cases.

If the system consists of a single pipe through which water is pumped at a constant rate at all times (Equation (17)), the velocity does bear a definite relation to the diameter for best economy for a given set of costs. Even for this special case, which is unusual in practice, the relation varies with the unit costs.

If the pumping rate is constant and the system consists of a network of pipes, even for a single set of unit costs, there is no single relation between the economic pipe size and the velocity. The size is determined by both the discharge through the pipe and the take-offs from the system.

If the layout is a gravity system, there is no relation between the velocity and the pipe size for best economy which is independent of the head available. There is no such thing, therefore, as an economic velocity for a given pipe size in a gravity system.

If the system consists of pipes through which water is pumped at a variable rate, the question arises immediately as to which discharge rate should correspond with the economic velocity. If it is assumed that the economic velocity should be determined from the average discharge through the pipe, it is found that it does not bear the same relation to the diameter as in the case of constant discharge. Moreover, since the economic diameter is affected by the manner of variation of discharge, the corresponding velocity is also affected in a similar manner. In this case, again, the take-offs from the system affect the relation of diameter to velocity for best economy.

APPENDIX

NOTATION

The symbols introduced in this paper are defined as follows:

A = a substitution constant (see Equation (21));

B = a substitution constant (see Equation (2));

C = cost of a series of gravity pipe lines; C_a = annual cost, in cents, of pumping, or of water power; C_c = first cost of laying cast-iron pipe, in cents per linear foot; C_f = cost of cast-iron pipe, in cents per pound, with freight allowed; C_l = cost of lead, in cents per pound; C_m = cost of materials, including cast-iron pipe, valves, fittings, and pipe lining, in cents per linear foot; C_p = cost or value, in cents, of raising 1 000 000 gal 1 ft; C_w = the wage rate for common labor, in cents per hour; C_y = cost of yarn, in cents per pound; C_{at} = total annual cost of pipe and pumping, in cents per linear foot of pipe;

C = Williams-Hazen coefficient;

c = cost of a section of pipe = $f(h)$;

D = diameter of pipe, in inches;

d = depth of pipe trench, in feet;

F = a coefficient giving the cost of different types of pipe at the trench, including contractors' profit, engineering, etc.;

f = function of: $f(h)$ = cost, c, expressed as a function of the head loss of the section;

H = total head available for loss in a series of pipe lines;

h = head loss through a single pipe or element;
l = length of sections of pipe;
m = ratio of take-off head to head lost by friction in the pipe;
Q = discharge, in cubic feet per second; Q_t = take-off discharge;
q = discharge through a single pipe or element, in cubic feet per second;
r = annual rate of interest plus depreciation of the pipe;
S = slope;
t = the design period; and,
w = weight, in pounds per linear foot.

DISCUSSION

Clinton L. Bogert[11] and J. M. M. Greig,[12] Members, Am. Soc. C. E. (by letter).—The clever formulas derived in Professor Camp's interesting paper exhibit to the writers the danger of carrying formulary regimentation into the realm of practical engineering. The writers question the economy of such formulas in office use. The formulas give a designer the exact diameter to fit a given set of fixed conditions; but, unfortunately, conditions do not remain fixed and, more important, cast-iron pipes are not made in the fractional diameters called for by the economical analysis, the designer being constrained to accept stock sizes which increase in diameters by relatively large steps.

A typical example, first solved by substituting in the formulas, and again by the usual trial methods with a Williams-Hazen slide-rule, for a compound line of two sizes and carrying diminishing quantities, required 2 hr to derive economical sizes of 23.2 in. and 19.0 in., respectively, and less than 10 min by slide-rule to arrive at stock sizes of 24 in. and 18 in., respectively.

Moreover, several of the "constants" assumed by Professor Camp as non-variables in the differentiation, are by no means constant in the practical sense:

(1) He assumes the price of cast-iron pipe as constant; bids taken by the writers' office in November were at least 30 cts per ft lower than they would have been if taken in August, 1937, due to the drop in cast-iron pipe prices;

(2) He assumes the quantity of water as a definite forecast, whereas adverse zoning restrictions, or the advent of a large industry, may upset the "picture"; and,

(3) He assumes that the Williams-Hazen-constant, C, is definitely known for a given time and place, whereas the quality of the water or corrective treatments of the water initiated at some future date may alter the values of C and the entire economic "picture" framed by the formula. The writers grant that these uncertainties also prevail in slide-rule analysis, but are less important as less time is involved.

They would qualify the assumption (see "Introduction") that the cost of elevated storage will not be influenced by changes in pipe sizes. It would not hold good in all cases. A certain water company has 17 tanks and stand-pipes and 41 wells spread over an area of 35 sq miles; some tanks are near wells and some distant. In this system the cost and allocation of future storage is influenced directly by the size and system of mains between one or more tanks and the centers of supply and the centers of demand, which are, of course, not collocated.

Charles M. Mower, Jr.,[13] M. Am. Soc. C. E. (by letter).—The often used "economic velocity" is not the correct standard for attaining true economy in distribution system design. The author has shown this fact clearly. The economic diameter of a pipe depends upon both discharge and take-offs from the system and upon unit costs of both pumping and pipes. In a system with a pumped supply, the two sources of power loss are loss of head in the pipes and take-offs at higher pressures than are required; but in a gravity system, the head loss in pipes costs nothing. The only losses which add to the cost of the gravity system are take-offs at pressures higher than those required where the excess is provided by pipes that are larger than necessary.

[12] Designer (Sanborn & Bogert), New York, N. Y.

[13] Hydr. Engr., Glenn D. Holmes, Syracuse, N. Y.

The author's assumption that pumping cost is directly proportional to head and discharge may be questioned since the capital cost of station and equipment and the operator's wages in a particular system are fixed regardless of considerable fluctuation in head and discharge. Since power is the only part of total pumping cost that bears a direct relationship to head and discharge, it would seem more logical to omit all fixed pumping costs from the equation just as the author omitted unpredictable pipe costs, and the cost of hydrant installations which were not affected by pipe sizes. However, in a practical problem, the result is not greatly changed by the use of power costs instead of total pumping cost, because pumping cost decreases much more rapidly with an increase in pipe diameter than pipe cost increases. Pumping cost varies inversely as $D^{4.87}$, whereas the cost of pipe laying varies directly as D and the cost of pipe materials, as $D^{1.55}$.

For the same reason, the total cost for a pipe one size larger than the most economical size is much less than the total cost for a pipe one size smaller. Thus, when computations indicate an odd pipe size, the next larger standard size should be used.

The methods of determining the pipe sizes for best economy for the different classifications of pumped supplies are just as applicable when a design is made on the basis of field tests of an existing system instead of the method suggested by the author, of dividing the system into districts and estimating domestic and fire drafts. In Case II particularly, there would be an advantage in having field measurements of the variations in flow for determining the value of A in Equation (23).

A. C. MICHAEL,[14] ASSOC. M. AM. SOC. C. E. (by letter).—For his attempt to rationalize the economic solution of complicated pipe-design problems, in which there are such a large number of variables, the author deserves to be commended. The mathematical derivations are very cleverly executed, except that certain assumptions and required adjustments might be questioned. The coefficients of the formulas are rather complicated, and, no doubt, considerable estimation would be required for their determination.

For very small systems, where the character of the water demand is simple, and where the piping arrangement is not complex, the method proposed probably could be used to advantage. The writer feels, however, that mathematical analyses of the problems of a water distribution system have a very limited application, and this is particularly true for a system of any size or complexity.

Of the variables considered in the formulas, many are extremely indeterminate. Costs vary over wide ranges; the cost of labor for laying parallel lines of the same diameter has been known to vary 50%, or more. The cost of pumping varies widely with changes in costs of fuel and labor and many other variables. The cost of excavation is usually an unknown quantity until after the work is completed.

---

[14] Asst. Mech. Engr., Dept. of Water Supply, City of Detroit, Dearborn, Mich.

The most difficult problem, which the author does not discuss, is the determination of average and maximum flow in a proposed pipe line. If a line is in a newly developed section of the city it is impossible to predict the ultimate water demand to be supplied. In many cases, a proposed pipe line is designed and ready for construction when it is learned that a new industry, using large quantities of water, is about to locate in the area to be served; it then becomes necessary to re-design the proposed pipe line and possibly parts of the existing system. This condition will continue until city zoning and planning ordinances have "teeth." The recent and rapid increase in air-conditioning installations is an example of how conditions change suddenly to cause existing piping systems to become inadequate. The careful development and study of population growth curves, per capita consumption, etc., may often be of little value after a depression in the business cycle has wrecked the trend of the established curves.

In addition to these factors, the variations in the daily load curve must be considered; the ratio of maximum hourly demand to the average daily demand is quite large, at times attaining a value of 3.0 or more. It is conceivable that a pipe having an economic diameter determined by the method described by the author would not have sufficient capacity to supply the maximum hourly demand.

Seldom is the engineer confronted with the problem of designing a complete water-distribution system. These systems grow gradually by the addition to, or extension of, existing lines. The usual problem is to select pipe sizes that will meet average flow conditions with normal pipe velocities, and maximum flow conditions with a respectable pressure at the consumer's outlets. The only suitable method open to the designer is to collect all the information possible, use all the tools and intuition he has at his command, and estimate the future average and maximum demand on the line or system. A size of line may then be selected such that, at maximum flow conditions, the pressure loss will be suitable and the velocity will not exceed a reasonable value.

ELLWOOD H. ALDRICH,[15] M. AM. SOC. C. E. (by letter).—In so far as it extends previous studies by Professor Camp and others into the analysis of water distribution problems, this paper should prove helpful in focusing attention on the economics of pumping and pipe installations. It sets forth a trial-and-error method to determine the economical sizes of pipe in water-works systems.

The various examples given in the paper cover, quite completely, the variable conditions that may prevail. The basic premise in all of them is that the economic installation depends upon balancing the cost of pipe line against the cost of pumping in comparative sizes of pipe. In the examples, apparently, trial-and-error methods must be utilized, first, to solve the distributional flow and then to determine the economic sizes of pipe under the assumed distribution. Quantities, depth of trench, and *m*, the ratio of take-off head to friction loss in the pipe (which, in turn, requires an assumption of pipe size), must be assumed and then rechecked.

---

[15] Cons. Engr., Reeves Newsom, New York, N. Y.

Several assumptions in the paper do not appear to be in accord with current practice. Granted that pumping is required, the only variable of any practical consequence in the cost of pumping is the cost of power or fuel. Capital costs of station and equipment are unaffected by the quantity pumped or the pumping head, within the ranges commonly applicable. Likewise, operating costs, exclusive of prime power, such as supplies and operating labor, are relatively stable and are little affected by quantity or head conditions. For the purposes used herein, if it is assumed that distribution storage is adequate to equalize hourly fluctuations in flow, accuracy will not be greatly sacrificed if the cost of pumping included only the cost of fuel or power.

One of the principal purposes of storage is to permit a decrease in pipe capacity. An economic study of the distribution of water cannot neglect the cost, effective elevation, location, and amount of storage in the system.

In some localities the so-called unpredictable costs of pipe laying, such as rock excavation, wet work, removal and relaying of pavement, and avoidance of obstructions, commonly add as much as 50% to the total cost of the work. Machine excavation, when applicable, and the use of composition joints and longer pipe lengths will lessen the cost of installing pipe. These unpredictable costs are not constant but vary with the size of pipe in about the same ratio as does the cost of laying. Therefore, they will affect the economic sizes of pipe appreciably since the higher cost of pipe construction will make more economical the use of smaller pipe with increased pumping charges.

In determining the economic size of a main over a period of years, consideration must be given to the total cost over the period. For instance, in comparing total costs of two sizes of mains with increasing demand over a period of years, the smaller main will have less total cost during the early years, due to lesser fixed charges, and more during the later years, due to increased pumping costs. For a true comparison between the total costs of the two mains, the savings of one over the other in the early years is greater than would be indicated by the formula in the paper because of the effect of compound interest. Furthermore, if water sales which will result from the installation of the smaller main are sufficient to pay the total charges in the early years of its use, substantial earnings above these charges will result from increased sales during the later years. The increased charges due to higher pumping charges, therefore, will be partly or entirely offset by increased earnings. This fact will justify the use of the smaller pipe with later duplication as required. This duplication will be largely paid for by the savings due to decreased capital costs in the early years and increasing earnings throughout the period.

The paper indicates that methods for analyses of distributional flow in pipe systems and for determination of the economic sizes of pipe have hitherto not been available and that in the past designers have not had practical methods for the solution of such problems. Graphical analysis of these problems, the fundamentals of which were illustrated by the writer in 1937,[16] have been in use by him for more than ten years and have proved quite adequate for the practical treatment of these problems. The determination of the economical sizes of pipe similarly yields to simple graphical analysis.

M. H. **Klegerman**,[17] Assoc. M. Am. Soc. C. E. (by letter).—There is an admitted reticence on the part of designing engineers toward the use of design methods involving intricate—or apparently intricate—mathematical procedures. Accordingly, they find their attention directed, from time to time, to certain design procedures, the advantages of which are acclaimed because of their "freedom from calculus," or "because they can be solved by simple arithmetic," etc. From the foregoing viewpoint one might, at first glance, relegate Professor Camp's formulas for the design of economic pipe networks, with their derivatives, integration, and exponential equations, to the "intricate mathematical type." That conclusion, however, bears no justification, as is disclosed by a little careful examination.

Much has been written about the ease of solving flow problems, for example, by means of the Williams-Hazen formula; but certainly, the solution of this formula, prior to the introduction of special slide-rules and tables for this purpose, was by no means simpler than any of the formulas for the determination of economic pipe sizes, as presented by Professor Camp. The same might be said for most of the existing flow formulas, such as those of Kutter, Manning, etc., the use of which has been simplified by means of tables, charts, and curves, so that the computer scarcely realizes that he is using rather "complicated" formulas. Therefore, one should not evaluate a new design method solely on the basis of time involved in its solution, by comparing to the time involved for the solution of an existing method, for which, as a product of long usage, special aids have been provided.

Simplification of design methods is indeed a virtue. Such simplification, however, is sometimes brought about through approximations, and under some conditions the degree of inaccuracy in the final solution of a problem may become very much in doubt, depending on the extent of such approximations. For example, in the solution of flow problems of pipe distribution systems, it is not uncommon practice to eliminate from the computations, for the purpose of simplicity, certain of the lines that a computer may "consider" of minor importance; or pay little, if any, attention to the effect on the flow distribution and pressure drops resulting from minor (but cumulative) take-offs. The extent of inaccuracies thus introduced is unknown. They may be insignificant under one set of conditions, but by no means so under another.

To overcome the foregoing objections, the designer is now provided with such devices as the Hardy Cross method[3] and others, the excellence and simplicity of which have already been well illustrated.[4]

---

[16] "Solution of Transmission Problems of a Water System," *Proceedings*, Am. Soc. C. E., October, 1937, pp. 1511–1533.

[17] Associate, Alexander Potter, New York, N. Y.

Similarly, Professor Camp has presented a tool that should prove of value in the economic selection of sizes comprising pipe networks, to which past efforts have been confined to "cut and try," and "experience," due to the admitted complexity of the problem.

Selecting the economic size of a single force main is a practise that is certainly followed by every engineer. Be that main relatively long, or even quite short (of the magnitude of 500 ft) a selection of diameter is based, among other factors, upon a consideration of the annual cost of financing the construction (including pipe, jointing material, laying, pumping equipment, etc.) and of the annual energy costs, these factors being plotted against pipe diameters resulting in a U-type of curve. Certainly, if such practise is warranted in the case of force-main design, there can be no question of the value of economic selection in the problem of distribution system piping, which represents, in total, vastly greater length and tonnage than the average force main.

The writer believes that the method presented by Professor Camp, used in combination with an exact method of determining flow distribution, has particular merit and application in the analysis of existing distribution systems for valuation purposes. For example, in the determination of a purchase price for public utilities (and the same may be said for rate determinations) one factor at least, in which the higher Courts have been in close accord, is the principle that it is the value of the property now, for which compensation must be paid now. As a result of the widely accepted principle, that "the expenditure required to produce a property as nearly as possible like the one valued, throws an important light upon value," most water supply valuation procedure, in so far as physical plant is concerned, involves the computation of "reproduction cost." This, in turn, requires the determination of a schedule of the property and consideration of the item of depreciation.

There are many cases of the valuation of water-works properties involving principally cast-iron pipe distribution systems, wherein reproduction cost has been determined by applying unit prices which were considered to be representative at the time of the valuation, to the inventory of the property involved, and deducting therefrom an allowance for depreciation. Thus, considering cast-iron pipe alone, having determined the length or tonnage, and adopted a unit price for these items, its "present worth" (deducting depreciation) was established.

The question, however, which did not receive adequate (if any) consideration in this case was: Does the schedule or tonnage of cast-iron pipe present in the distribution system, represent the least tonnage required to serve the same streets at equivalent hydraulic capacities? If it does not, why should the purchaser be required to pay for unnecessary pipe tonnage? Particularly, if he were to reproduce the system, he would, it is properly assumed, design the most economical distribution system possible for the hydraulic conditions represented by the system being valued.

Perhaps this viewpoint is contrary to the generally accepted meaning of the term, "reproduction cost," which refers to the cost of a structure in all respects identical with the old one; nevertheless, it may safely be stated that if the enterprise being valued were completely destroyed, the chances of replacing it exactly as it was before would be remote. In other words, the worth of a new plant of equal capacity, efficiency, and durability, with proper discounts for defects in the old plant (and, of course, depreciation for use) should be the measure of value, rather than the cost of exact duplication.

The drawback to the acceptance of this viewpoint, calling, in effect, for new design, has undoubtedly been due to the fact that in the absence of analytical design procedures, engineers would differ widely in such "equivalent" designs.

It is realized that "excellence of design" receives consideration in valuation work. However, without the relatively recent methods of computing flow distribution, quickly and accurately, in various parts of the water supply distribution system, and in the absence of a method of determining the most economical network of pipe sizes required in it, such weighting of "excellence of design" in determining value is relegated, necessarily, to the realm of opinion. To eliminate this opinion (which tends to vary with individuals) and to substitute for it an analytical method capable of identical solution by independent computers, would be a step forward in the reduction of the indeterminate factors that make valuation work controversial.

In applying the various Camp formulas to a study of an existing system (that is, for determination of least tonnage for an hydraulically equivalent system) the availability of flow records and billings, particularly in metered systems, would make possible fairly accurate estimates of take-offs. Fire flows for the determination of maximum flow conditions, as is required in some of the cases presented, could be determined from field tests. Friction coefficients could also be determined from field tests, the work being confined to representative mains in order to classify coefficients of the mains for various age groups. The extent of this determination may be carried to any degree required. However, as the author indicates, inasmuch as a reduction of the value of *C*, as great as from 130 to 80, will produce a variation in economic diameter of only 15%, probably typical coefficient values only need be determined by field tests. Power costs at the time of valuation can be determined definitely.

Thus, many of the factors entering into the use of the Camp formulas (as applied to analysis of existing systems) are quite capable of practical determination. Other factors, as to laying costs, etc., can probably be revised, if necessary, to apply to specific conditions.

F. KNAPP, ESQ.[18] (by letter).—There has been no good compendium on the subject of economic sizes of pipes for water distribution systems and, therefore, the paper by Professor Camp is a timely one. The author is to be commended, especially, for his attempt to classify the several cases met with in practice.

As far as the economic diameters for a gravity system are concerned, the writer understands that the method proposed by the author consists in simplifying the network so that only the larger and important mains are shown. To this series of pipes, Equation (13) or Equation (14) is applied, thus determining the best diameters. Applying this procedure to a distribution system, such as that shown in Fig. 4 (*a*), the mains would consist of Pipes 1, 2, 3, 4, and 5. With these diameters fixed, the sizes of the pipes of the remaining network are determined in such a manner that all, or nearly all, the available head is utilized. With the critical point at *k* instead of *a*, the procedure is repeated, but as the economic diameters for the several loading conditions will not be identical, some standard size of pipe will be selected which comes nearest to satisfying all the loading conditions.

---

[18] With the São Paulo Tramway, Light & Power Co., Ltd., São Paulo, Brazil.

This method assumes that the sub-branches are relatively small as compared with the main pipes. Assuming, however, that the take-offs of a network system are distributed in such a manner as to require pipes of about the same size, it is certainly not admissible to "skeletonize" the system. In this case, the flow in each pipe is known only after the pipe system has been analyzed, assuming or estimating the diameters. How would the author proceed in such a case?

The writer is unable to follow Rules (1) and (2) as formulated in the text following Fig. 2, and as the treatment of the economics of pumped supplies makes direct use of these rules, the writer hopes that the closing discussion of the author will clear up these points.

THOMAS R. CAMP,[19] M. AM. SOC. C. E. (by letter).—In the preparation of this paper, it was the writer's purpose to contribute in a small way toward the development of effective and reliable means for the design of water distribution systems and reinforcing mains. As is well known, the analysis of flow in distribution systems is extremely complicated. Since reliable methods for the solution of the many hydraulic problems relating to distribution networks have been made available only recently, it is small wonder that so little has been done regarding the rational approach to methods of selecting the most economical sizes of pipes. Nevertheless, the selection of economic pipe sizes is of as much importance to the engineer in the design of distribution systems as is the correct solution of the hydraulic problems.

A most necessary part of engineering design is the selection of sizes and shapes for best economy. In the design of most engineering works, considerable time and effort are expended to obtain a workable layout at a minimum cost. The engineer has prided himself on being able to "build for one dollar what any other fool can build for two dollars." The *raison d'être* of the engineer, particularly the consulting engineer who engages in the design and supervision of construction, is his ability to produce a workable design at a minimum cost of construction and operation.

Messrs. Bogert and Greig profess to see in the writer's formulas a "danger of carrying formulary regimentation into the realm of practical engineering," presumably because of the lack of "economy of such formulas in office use." It is not necessary to use the formulas themselves for office use. They merely express the fundamental relations. Any engineer who desires to apply economic principles to the design of pipe networks may simplify the use of the formulas, or other similar ones, by preparing charts or slide-rules. This is what has long since been done for many of the complicated pipe-friction formulas, as has been so well pointed out by Mr. Klegerman. The time required for the use of the formulas for economic pipe size will be quite short as compared to the time that will be required to solve for the flow distribution after the selection of each trial set of economic pipe sizes. The writer is not attempting to submit a method of design that is easier than methods now in use. He is submitting fundamentals underlying a procedure which heretofore has not been used at all for complex networks.

---

[19] Associate Prof. of San. Eng., Mass. Inst. Tech., Cambridge, Mass.

The client can well afford to pay the cost of many times the office work usually required for the design of distribution system reinforcements if this additional work results in substantial savings in over-all costs. That substantial savings are possible cannot be doubted, because the sums involved in distribution system construction are tremendous. C. Maxwell Stanley,[20] Assoc. M. Am. Soc. C. E., has shown that the costs of a number of distribution systems in Iowa represent between 41% and 85% of the total values of the water-works. According to George A. Sampson[21] the distributing pipes represent about 90% of the value of small New England water-works; and according to W. W. Brush,[22] M. Am. Soc. C. E., about 50% of New York City's waterworks investment of a half billion dollars is in the distributing system. Since the cost of water-works is from about $24 to about $70 per person served, the enormous investments involved in distribution pipes are quite apparent.

Messrs. Bogert and Greig, and Mr. Michael, criticize the writer's formulas because the coefficients, costs, and demand rates are not constant and are difficult to estimate. This is true, of course, for any method of design which involves predictions of future conditions. Nevertheless, it is necessary to make such predictions in order to proceed. Fortunately, the effect of errors in these estimates is not so great upon the economics as it is upon the workability of the design. The cost of a pipe line and pumping, plotted against the diameter, results in a U-shaped curve which is quite flat in the immediate vicinity of the most economic diameter. The cost, therefore, is not affected appreciably by the selection of the commercial diameter nearest the economic size. Similarly, errors in the estimation of any of the coefficients or other factors to be introduced into the formulas do not result in errors of the same magnitude in the diameter or cost.

An error of only 5% in the economic diameter of pipe requires, for its production, much larger errors in each of the factors in the formulas. The estimated discharge must be in error by at least 11%; the friction factor, C, by at least 18%; the pumping cost by at least 35%; the rate of interest plus depreciation by at least 35%; and the cost of laying, the cost of cast iron, or the value of Factor F, must be in error by more than 35 per cent. Hence, precision in the use of the formulas is not warranted.

For the same reason it is of little consequence whether total pumping cost, or only power cost, is used; and the error involved in the assumption that total pumping cost is directly proportional to the head and to the discharge is of little moment. These points have been recognized by Mr. Mower and by Mr. Aldrich.

[21] Paper presented at the September, 1938, meeting of the New England Water Works Assoc. (Not yet published.)

[22] *Loc cit.*

Messrs. Bogert and Greig, and Mr. Aldrich, are concerned regarding the assumption that the cost of elevated storage is unaffected by changes in pipe size. As stated by Mr. Aldrich, "one of the principal purposes of storage is to permit a decrease in pipe capacity." This is correct for the pipes from the supply to storage, but if the storage is more than adequate for hourly fluctuations in demand, the quantity of storage is not related to pipe sizes. Hence, the cost of storage is not related to pipe size, except as the cost is influenced by the elevation of the stored water. The foregoing considerations are based upon the assumption that the locations of the reservoirs are fixed by the topography.

If the locations of the distributing reservoirs are not fixed by the topography, a much more complicated economic problem arises. In flat terrain where elevated storage must be provided in elevated tanks, the choice of the number of tanks and their locations is unlimited. In such a case economic pipe sizes are certainly affected by the location of the storage. The economic considerations leading to the location of distributing reservoirs are outside the scope of the paper. It is manifestly impossible, in one paper, to consider all the possible cases and conditions that might arise in the design of such complex works as distribution systems.

Mr. Michael suggests that "it is conceivable that a pipe having an economic diameter determined by the method described by the author, would not have sufficient capacity to supply the maximum hourly demand." Since the capacity of a pipe depends upon the head provided for flow and the writer's method fixes the head by fixing the elevation of the storage, this difficulty will not arise. It will be found occasionally, however, for cases with widely fluctuating draft, that pressures in the mains will be so great that the computations must be revised using heavier pipe than was originally contemplated. In some cases it will also be found that pumping heads are so great that it will be necessary to revise the computations with the additional pumping equipment costs taken into account.

Mr. Aldrich states that the so-called unpredictable costs, such as rock excavation, wet work, removal and relaying of pavement, and avoidance of obstructions are not independent of pipe size as claimed by the writer, but vary with the size in about the same ratio as the cost of laying. He is quite correct in the case of pavement, but the cost of pavement removal and replacement is predictable and may well be included in the equations of cost. The cost of wet work (sheeting, bracing, and pumping) and avoidance of obstructions is, in most cases, influenced very little by differences in pipe sizes. The cost of rock excavation is influenced by pipe size, but it is not directly proportional to pipe size. According to Mr. Sampson[21] the rock excavation for a number of New England systems averaged 150 cu yd per mile. The cost of this quantity of rock is less than 8% of the total cost of the mains. Where rock excavation is known to be required in considerable quantities, it can be included in the equations of cost.

The effect of compound interest upon the economic pipe size is of little consequence. It has been accounted for in the writer's equations in the form of depreciation. The factor, r, is the rate of interest plus depreciation. Large errors in the assumed value of r are required to produce appreciable errors in the economic pipe size.

Mr. Klegerman has performed a service in emphasizing the possibilities of using the methods presented in this paper for valuation work. It is probable that many difficulties would arise in securing the acceptance of the procedure outlined by Mr. Klegerman in Court cases, but as the method of hydraulic and economic analysis of distribution networks is perfected and simplified, it is certain to find a place in valuation work.

Mr. Knapp, quite properly, questions the validity of the practice of "skeletonizing" the distribution system when there is little difference in size between the trunk lines and the branch pipes. This criticism applies to the hydraulic analysis only, since the size of the branch pipes is commonly fixed at a minimum consistent with good fire protection (6 in. in the United States) without regard to economic diameter. In spite of the fact that the writer has quite naively described the "skeletonizing" process as a part of the method of attack in design, and despite the fact that much has been written by others relative to "skeletonizing" and many engineers have resorted to this practice, it is certainly not permissible to "skeletonize" any system without some knowledge of the magnitude of the errors that will thus be introduced into the hydraulic computations. So far as the writer is aware, no practical method has yet been presented for determining the magnitude of the errors due to the neglect of the smaller pipes in the hydraulic computations of a grid system. This problem appears to be one which has not yet been properly examined.

Rules (1) and (2) for estimating the take-off power loss are somewhat involved and have doubtless not been stated as clearly as is desirable. Two rules are required since the power is a function of both head and discharge and estimates of each must be made. The excess head at Point b is represented by the height of the heavy line, h_b, on Fig. 2(b). This head is all chargeable to Pipe 1, for if this pipe were made large enough, this head loss could be avoided. No more than this amount of head loss could be avoided by such procedure, however, without infringing upon the required residual head at Point b. The heads chargeable to the other pipes are shown on Fig. 2(b) as h_2, h_d, h_4, and h_5 at the up-stream ends of the pipes. The power losses corresponding to each of these heads are estimated from the average rates of discharge which must be pumped against these heads and which are taken out of the system at points up stream from the corresponding pipes.

GRIT CHAMBER MODEL TESTS FOR DETROIT, MICHIGAN, SEWAGE TREATMENT PROJECT

BY GEORGE E. HUBBELL,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. G. M. RIDENOUR, THOMAS R. CAMP, W. E. HOWLAND, AND GEORGE E. HUBBELL.

SYNOPSIS

In designing the grit chambers for the Sewage Treatment Plant, at Detroit, Mich., in 1936, several problems were solved by means of a small-scale model of the tank and large-scale tests of two existing tanks. The small model was used to observe flow distribution and grease removal, and the large-scale tests revealed the percentage removal of sand of various sieve sizes for any given length of tank. This paper presents actual data on the settling of sand in flowing water, under field conditions, in a form which greatly simplifies the computations involved in grit-chamber design. This is not a theoretical approach to the problem of sedimentation in flowing water, but rather a presentation of data in a practical and usable form heretofore not available to the sanitary engineer.

INTRODUCTION

Cost estimates of the grit chambers at Detroit indicated that a saving of $167 000 could be made by adopting a design consisting of grit chambers, 150 ft long by 15 ft deep, instead of the customary tanks, 75 ft long by 7.5 ft deep. The unusual depth of the proposed chambers raised a question as to their effectiveness for grit removal; and also as each unit was designed to handle a flow of 250 cu ft per sec, the matter of entrance configuration in changing from a velocity of 4 ft per sec to 1 ft per sec required careful consideration. Since the effluent from the grit chambers was to be transported to the settling tanks through submerged conduits, the problem of coercing grease and floating material into the conduits arose. Recourse was made to the performance of a small-scale model for flow distribution and grease removal, and field tests were made on two existing grit chambers for the data on sedimentation of sand in flowing water.

NOTE.—Published in December, 1937, *Proceedings*.

Laboratory Tests of a Small-Scale Model

Description of the Model.—A one-fifteenth scale model was constructed of wood and equipped with a glass side wall for observation of flow distribution. The principal dimensions of the prototype are given in Fig. 1. The model was operated in accordance with the Froude model law,[2] the actual flow in the model being 130 gal per min with an average velocity in the model of the grit chamber proper of 0.26 ft per sec. The supply was from a constant head tank entering through a calibrated valve. In the prototype the screen or rack consisted of bars, 3 in. by 0.5 in., with 0.75-in. openings. This screen was modeled of brass strips, 0.2 in. by 0.031 in., with a clear opening of 0.05 in.

Flow distribution was observed by introducing coloring matter, sawdust, and fine sand into the model. Observations indicated the following:

(1) There were no dead areas in the grit chamber;

(2) Flow followed the divergence angle of 2 on 5 in passing from the screen section, 12 ft wide, to the grit chamber section, 16 ft wide, without creating back eddies;

(3) Flow followed the bottom configuration in the approach to the rack, the slope being 2 ft on 5.26 ft;

(4) Flow followed the bottom configuration from the rack to the grit chamber, the slope being 2 ft on 3.77 ft;

(5) Coloring matter moved with an approximately vertical front in a remarkably uniform manner through the grit chamber (the first color flowed through in 74% of the theoretical time of 25.6 sec, the main body in about 90%, and the last color in 130%, of the time); and,

(6) No unusual horizontal or vertical velocity was observed. Coloring matter placed on one side of the channel remained on that side throughout the length of flow.

---

[2] "Hydraulic Laboratory Practice," Edited by the late John R. Freeman, Past-President and Hon. M., Am. Soc. C. E., A. S. M. E., New York, N. Y., 1929.

The grit chamber actually adopted (see Figs. 2 and 3) conforms closely to the dimensions of the prototype shown in Fig. 1, except that the length was increased to 150 ft.

Screen.—The excellent distribution obtained is attributed to the inclined bar screen or rack. The tests were conducted with a rack having a slope of 1 horizontal to 3.44 vertical. Variation in the angle of slope of the screen had little effect on flow distribution.

Oil and Scum Removal.—Floating matter was removed from the surface of the model by means of the sloping top of the outlet conduit. A slope of 1 vertical to 4 horizontal is required to prevent undue accumulation of oil and grease. In the model, the draw-off velocity was 1.29 ft per sec, corresponding to a velocity of 5 ft per sec in the prototype. Since the effluent from the grit chambers is carried in submerged conduits to the sedimentation tanks, and since no mechanical means for grease removal will be installed in the grit chamber, it is important that all such matter be forced into the outlet conduit.

Settling of Sand in the Model.—When the investigation was first undertaken, it was felt that perhaps data could be obtained from the model relative to the manner in which sand would settle in the prototype. Direct application of the Froude law of model similitude would indicate that volumes to be used in a one-fifteenth scale model should be 3 375 times as small as the corresponding volumes in Nature. This would indicate that a 0.2-mm sand grain in the prototype would be the finest of dust in the model. In arriving at a proper grain diameter to use in the model, the following assumptions were made:

(1) Particles with diameters ranging from 0.2 mm to 0.1 mm settle in still water at constant temperatures in accordance with the expression,

$$V_s = k\, D^n \qquad (1)$$

in which V_s = velocity, in millimeters per second; D = diameter of particle, in millimeters; and, k and n = constants to be determined experimentally.

(2) The horizontal velocity, V_h, of the water in the model varies in accordance with the Froude law, $\frac{1}{\sqrt{l}}$, of the velocity in the prototype, in which l = a scale ratio for length $= \frac{L_n}{L_m}$; L_n = any linear dimension in the prototype (in Nature); and L_m = any linear dimension in the model.

(3) That it is desired to settle a particle having a settling velocity, V_s, a vertical depth, d, while the same particle moves forward with a horizontal velocity V_h a distance, L, in which d = the depth of a tank, in millimeters; and, L = the length of a tank, in millimeters.

Let the settling time, $t_s = \frac{d}{V_s}$; and, the time for corresponding horizontal movement, $t_h = \frac{L}{V_h}$. Then, for $t_s = t_h$:

$$V_s = \frac{V_h\, d}{L} \qquad (2)$$

FIG. 3.—SECTIONS OF RACKS AND GRIT COLLECTORS

To obtain the ratio of grain diameter in the prototype to grain diameter in the model, equate the ratios of Equations (1) and (2): $\left(\frac{D_p}{D_m}\right)^n = \frac{l\sqrt{l}}{l}$ and,

$$D_m = \sqrt[n]{\frac{D_p^n}{l}} = \frac{D_p}{l^{1/2n}} \quad \text{.......................} (3)$$

Although the foregoing development appears to be rational, the application has various limitations. For example, it is assumed that a logarithmic expression can be written for the manner in which sand settles in still water (Assumption (1)). If the particle size remained in the region governed by Stokes' law, or Newton's law, this might be done; but sand 0.2 mm in diameter lies in the critical region where the law of subsidence changes.

Stokes' law (see Assumption (2)) is true for particles settling in quiescent water. It does not hold for settlement in moving water in which, obviously, certain eddy currents occur due to turbulent flow conditions. Much information is available on the transportation of sediment by flowing water[3] but little is available on the sedimentation of material in flowing water at the velocity encountered in grit-chamber practice. In the prototype the average horizontal velocity is 1 ft per sec whereas in the model it is 0.26 ft per sec. Thus, it would appear that model results indicate greater removal than would actually occur in the prototype.

To operate the model in order to obtain data on the removal of sand, 0.2 mm in diameter, in the prototype (Assumption (3)) requires that sand having a diameter (by Equation (3)) of 0.10 mm be obtained for use in the model. Tyler sieves of 150 and 140 mesh have nominal openings of 0.104 and 0.107 mm, respectively. In the prototype, this range of size would correspond to 0.212 mm and 0.218 mm. Quartz sand, 0.1 mm in diameter, is not spherical, but rather is composed of angular particles of various shapes. In arriving at the required model size, it is assumed that the particles are spherical and of uniform size. Both these assumptions are difficult to achieve.

FIELD TESTS OF LARGE-SCALE MODELS

Because of the inherent difficulties involved in the conduction and interpretation of small-scale tests of sand deposition, recourse was had to two existing grit chambers where tests could be conducted at a velocity in the grit chamber of approximately 1 ft per sec. Although the foregoing comment shows that it is possible to test small-scale models, it is quite evident that the use of a large-scale model in which the velocity ratio is 1.0, materially reduces the number of required assumptions for a transfer of results from model to prototype. Two tests were conducted, one at the sewage treatment works in Grand Rapids, Mich., and one at the East Side Sewage Treatment Plant, in Dearborn, Mich. Both tests were run to obtain data on the manner in which sand of various particle sizes settled in water flowing with an average velocity of 1.0 ft per sec. Actually, due to conditions surrounding the tests, the average velocity was

---

[3] "Transportation of Detritus by Flowing Water," by F. T. Mavis, M. Am. Soc. C. E., Chitty Ho, Assoc. M. Am. Soc. C. E., and Yun Cheng Tu, Univ. of Iowa *Bulletin No. 5;* and "Transportation of Débris by Running Water," by G. K. Gilbert, *Professional Paper No. 86, U. S. Geological Survey.*

0.9 ft per sec. Two tests were necessary in order to substantiate the following theoretical development as to interpretation of test results.

Referring to the development of Equation (2), $\frac{L}{V_h} = \frac{d}{V_s}$; or, in terms of ratios: When the V_h-ratio = 1 and the V_s-ratio = 1, the L-ratio is $l = \frac{1.0}{1.0} \times h$-ratio. That is, the length ratio must be equal to the height ratio. Thus, in the model, if the height ratio is 2.0, and 60% of the sand of a given size is removed in 100 ft of tank, then in the prototype the same percentage removal of sand can be expected to occur in 200 ft. Since, in the settling of sand, there is no coagulation action, this conclusion appears rational and is substantially in accord with observations.

Grand Rapids Test.—Fig. 4 shows the general plan of the grit chamber tested. The channel selected was thoroughly cleaned for the test. Under normal flow conditions, the average depth in the channel is 4.7 ft. In order to secure a greater depth, the treatment plant was shut down and the sewage allowed to store in the influent sewer. When it had reached the lip of the overflow, all the sewage was passed through the selected channel, giving a depth at the midpoint of the grit chamber of 6.13 ft at the beginning of the test to 6.00 ft at the end of the test. When flow conditions had become constant, as evidenced by a uniform water level and Venturi meter readings, sand was fed into the grit chamber with shovels by two workmen standing on the platform at Elevation 18.0, dropping the sand into the water at Elevation 15.2. The sand was placed in the narrow end of the curved entrance channel (4 ft wide by 4.5 ft deep). The velocity in this approach section averaged 2.4 ft per sec. The sand was measured in a container having a volume of 0.77 cu ft which held 74.5 lb of sand, measured moist. No determination of moisture content was made. The same container was used to measure the sand removed by the chamber. The test was made on Friday and the grit chamber allowed to drain and dry until the following Monday. It has been assumed that bulking was the same during both sets of measurements. Fig. 5 shows the weight of

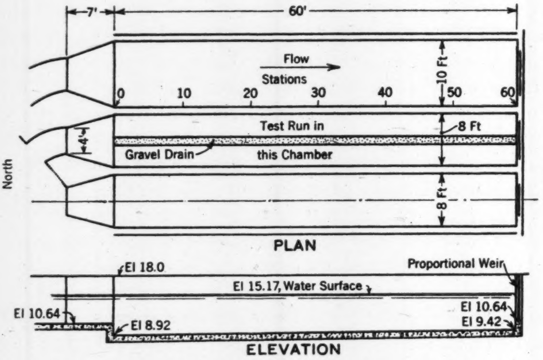

Fig. 4.—Plan of Grit Chamber, Grand Rapids, Michigan

sand deposited in each 10-ft section of the chamber. The sand was carefully scraped into piles, a sample was taken in accordance with the A.S.T.M. standard method of sampling, and the volume determined. It was estimated that 0.5 pail of sand was deposited on top of the central gravel drain that runs the entire length of the chamber. This half pail of sand has been prorated to the various sections. Fig. 6 shows the velocity variation in the channel, the average of all readings being 0.901 ft per sec. There was an unequal distribution over the cross-section, the velocity on the east side being consistently greater than that on the west side.

* Numbers in parentheses are percentages. † Sample of sand added to chamber.

accurate to 0.10 gram, and the percentage composition of each sample was determined. Knowing the percentage composition of each sample and the actual weight of sand from which the sample was taken, the quantity of sand of each sieve size removed in each 10-ft section of the grit chamber was computed. (The average water depth was 6.0 ft; the temperature of the water was 65° F; the nominal velocity of the water was 0.90 ft per sec; and the specific gravity of the sand was 2.65.) The relation between the percentage removal of sand, of a given sieve size, and the length of tank required to obtain this removal, is best shown by means of the semi-logarithmic plat. Fig. 7 treats the data for the plant at Grand Rapids in this manner. It appears that these curves can be extrapolated as straight lines, all values beyond the 60-ft length being so obtained.

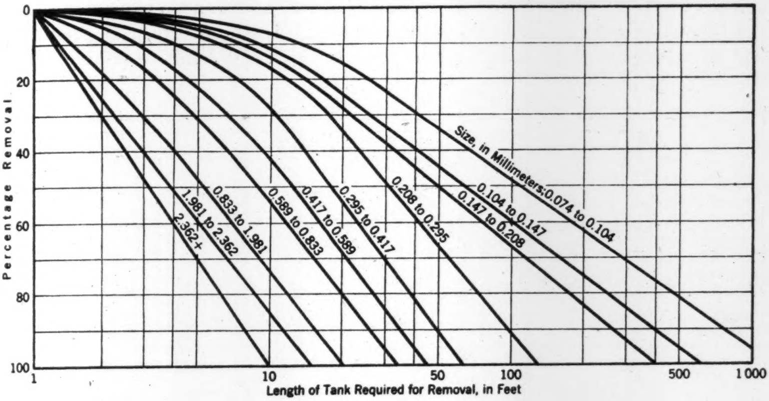

FIG. 7.—PERCENTAGE REMOVAL OF SAND OF VARIOUS SIZES, BY GRIT CHAMBER, AT GRAND RAPIDS, MICHIGAN

Dearborn Test.—Fig. 8 shows the general plan of the grit channel tested at the East Side Plant. The sewage is raised to the chamber by two pumps having a combined capacity of 6.5 cu ft per sec so that it was possible to adjust the effluent weir to obtain an average velocity of 0.9 ft per sec, the average depth being 2.8 ft. The actual velocity during the test, as obtained by float measurements, varied from 0.89 ft per sec to 0.96 ft per sec and averaged 0.93 ft per sec.

FIG. 8.—PLAN OF GRIT CHAMBER, DEARBORN, MICHIGAN

The high entrance velocity was dissipated by means of two baffles, the first consisting of a solid plank 24 in. high placed at the bottom, the second being a vertically slotted arrangement made of 1-in. by 3-in. strips. However, turbulence persisted in the first 20 ft of the chamber, but beyond that point flow conditions were uniform.

In order to obtain a wide variation in the composition of the sand placed in the chamber, 990 lb of coarse sand, 673 lb of medium sand, and 1 587 lb of fine sand, were fed to the channel on an inclined board so that the drop to the water surface was 6 in. In this test all of each grade of sand was fed continuously, in the following order: Coarse, medium, and fine. In the future, this procedure will be avoided as it gives a stratified deposit which is difficult to sample. The weight and location of the sand deposited in the grit chamber are shown in Fig. 9.

Results of Tests.—The laboratory and field model tests were conducted to enable the prediction of the grit removal to be expected from a tank having an effective depth of 15 ft and a length of 150 ft.[4] Based on a test run of the

---

[4] It is recognized that, in general, the term, "grit," is all inclusive and covers all material settling out in the grit chamber. As here used, it refers only to material similar to sand, abrasive in nature, the Detroit grit chamber functioning only to protect the mechanical equipment for sludge handling. Sand embedded in the sludge removed from grit chambers may not have the same mechanical analysis as the sand used in the tests reported on. This, however, has no effect on the removals for a given sand size.

	True, small-scale model, laboratory test	Field test, Dearborn, Mich.	Field test, Grand Rapids, Mich.		True, small-scale model, laboratory test	Field test, Dearborn, Mich.	Field test, Grand Rapids, Mich.
(1)	(2)	(3)	(4)	(1)	(2)	(3)	(4)
Scale	1 : 15	1 : 5.35	1 : 2.5	Scale	1 : 15	1 : 5.35	1 : 2.5
60	72	..	40	120	90	63	65
80	79	37	50	140	94	73	70
100	85	50	59	150	96	77	73

As might be expected the laboratory model indicates a greater percentage of removal than the field models. This can be explained in part as due to the reduced turbulence corresponding to a lower velocity in the small model. The results based on the field tests for this sand size are in close agreement for the greater length values. For other sand sizes, the variation is greater, the Dearborn test generally indicating greater lengths for the same percentage removal. It is assumed that velocity-variation effects were the same in both tests and will be the same in the prototype. Undoubtedly, the distribution in the prototype will be more uniform, with consequent greater removals. Fig. 11 gives the expected removal for a tank of 15-ft effective depth. The removals shown are based on the Grand Rapids test and represent the writer's judgment in interpreting the available data.

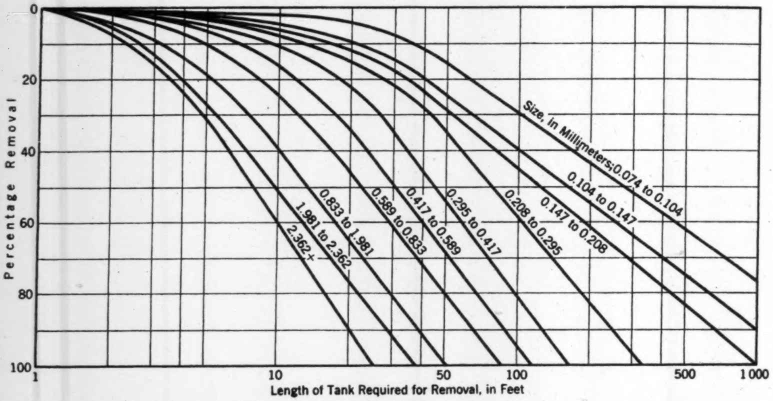

FIG. 11.—EXPECTED PERCENTAGE REMOVAL OF SAND IN TANK, 15 FEET DEEP, BY DETROIT GRIT CHAMBERS

Size of Sand Reaching the Settling Tank.—In setting up the requirements for the grit chamber the Board of Consulting Engineers (Clarence W. Hubbell, M. Am. Soc. C. E., the late Harrison P. Eddy, Past-President, Am. Soc. C. E., and the late John H. Gregory, M. Am. Soc. C. E.) stated that "tests should be run to determine: (1) The possibility of depositing all sand greater than a 0.2-mm effective size; and (2) the length of flow required for such deposition." This may be interpreted as meaning that it would be desirable to deposit all sand having a size greater than 0.2 mm.[5] Table 4 gives a sieve analysis of the sand content of sludge or grit removed from the Grand Rapids grit chamber and from sludge obtained from the final digestion tank. An analysis is included of a catch sample of sand found at the curb of a city street where the soil is clay, with well kept lawns.

---

[5] "Grit Chamber Practice": A Symposium, *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 495.

Of the sample of grit removed from the digested sludge, 54.5% was retained on a 65-mesh screen, or was larger than 0.2 mm. Analysis was made possible by treating the sludge with acid to remove the organic material. Apparently, this grit does not cause excessive wear on the mechanisms in the plant. Presumably, then, it is not necessary to remove all the grit of this size in a grit chamber. The field tests indicate that the Detroit chambers will not remove all the grit coarser than 0.2 mm.

* Large particles of silt cemented together.

In analyzing the Detroit grit chambers, Eugene A. Hardin, M. Am. Soc. C. E., prepared the material in Table 5, based on the foregoing tests and an analysis of an assumed sample of grit (Column (3)), which indicates that the Detroit chamber, 15 ft deep by 150 ft long, will remove 17% more grit than one 100 ft long, and 72% more than one 50 ft long. Comparing this tank with one of equal length, but 6 ft deep: At 150 ft the 15-ft tank removes 19% less than the 6-ft tank; at 100 ft, 26% less; and at 50 ft, 38% less. The economic length of the grit chamber would appear to be not more than 100 ft since the extension of the tank to 150 ft will increase the total removal only 17% and effect this in the range of grit smaller than 0.3 mm in diameter. It was estimated that the increase in length from 100 ft to 150 ft would cost $75 000. This expenditure seemed warranted in Detroit for the following reasons: The tanks were unusually deep, with no similar tanks available for comparison; and the increased length would reduce the solids load on the settling tanks to some degree and would act as a factor of safety insuring a minimum of grit passage to the sludge disposal mechanism. However, the writer believes that a grit chamber, 150 ft long, is not necessary.

CONCLUSION

It is hoped that this brief description of a method of approach to the grit-chamber problem will result in other similar investigations. Theoretical computations for sand removal in grit chambers are uncertain, due to the difficulty of evaluating the various factors involved, whereas the results obtained from tests are substantially correct and practical in application.

A laboratory approach to the problem has been indicated which may be of value, although it is felt that more reliable information is gained by eliminating the velocity factor.

Excellent flow distribution can be obtained by means of bar screens having $\frac{3}{4}$-in. openings. Such screens introduce sufficient loss of head to insure uniform velocity conditions during grit deposition. Grease can be induced successfully into submerged conduits by using a draw-off velocity of 5 ft per sec and conduit roofs having slopes of less than 14 degrees. In large installations, deep grit chambers proportioned so that uniform velocity conditions exist, are more economical to construct, and will perform with the same degree of efficiency as grit chambers of one-half the depth and length and twice the width.

ACKNOWLEDGMENTS

The writer wishes to acknowledge the valuable suggestions offered by Albert Roth, Assoc. M. Am. Soc. C. E., Arthur B. Morrill and Eugene A. Hardin, Members, Am. Soc. C. E.; and, for making the field work possible, he is grateful to James R. Rumsey, M. Am. Soc. C. E., former Sanitary Engineer for the City of Grand Rapids, and Austin Habemehl, former Chief Chemist at the Dearborn Plant.

DISCUSSION

G. M. Ridenour,[6] Assoc. M. Am. Soc. C. E. (by letter).—An interesting approach to a more rational and scientific development of grit chambers is presented in this paper. The similarity to large-scale results in the model, operated in accordance with the model law, is encouraging to further investigation along this line, and the author is to be commended for introducing this method of study.

The difficulty of comparing the effect of depth on the performance of large-scale grit chambers which at the same time vary in so many other respects, such as surface area, volume of flow, distribution of velocities, and ratios of length to width and depth, however, would appear to be great. This seems especially true due to the sensitivity of settling sand to various influences and the exacting relationships of economic calculations.

In view of the seemingly variable conditions between the Grand Rapids, Mich., and Dearborn, Mich., units, the writer wonders whether it is not possible to arrive at conclusions that differ from those presented in the paper, depending on interpretation, and tending to show that the shallower grit chambers might be the more efficient, even at the sacrifice of losing the equality of the theoretical relationship of $\frac{d}{v_s}$ to $\frac{1}{v_h}$ which seems to be the basis for the conclusions in the paper.

From the data presented, the writer has compared the efficiencies of the two units in three different ways: (*a*) On the basis of total percentage of grit removed; (*b*) with respect to the average size of sand removed in succeeding sections of the tank; and (*c*) comparative performance on the basis of equivalent surface areas. The computations are shown in Table 6.

The sieve analysis of the materials removed in each section of the grit chamber shows that, in general, the shallower grit chamber at the Dearborn plant removes a sand of much less average size in equivalent sections of the tank. This action holds throughout the tank length with the exception of the first section which is admittedly adversely influenced by the turbulence of the pumps. Table 6 also shows that the percentage of total sand removed is slightly greater in the Dearborn plant in each succeeding section of the channel, again with the exception of the first 10 ft.

Another observation that can be made from the data is the critical size at or below which the percentage of small sand in the composite sample increases toward the outlet end, indicating that point at which the $\frac{1}{v_h}$-ratio exceeds the $\frac{d}{v_s}$-ratio. In the Dearborn plant this size lies between 0.104 and 1.47 mm. In the Grand Rapids plant, the critical size lies between 0.295 and 0.417 mm.

Additional comparisons have been made in Table 6 on the basis of efficiency in relation to equivalent surface area. A sand, 0.2 to 0.3 mm in size, has been used for the calculations, the same as that used for the design of the Detroit plant. These computations seem to confirm the previous generalizations that a greater efficiency can be expected from the shallower unit, provided exception is made of the poor performance in the first 20 ft of the Dearborn chamber due to pumping disturbances. The end of this section is situated at the equivalent surface area of 256 sq ft of the Dearborn unit. The efficiency of the shallower unit is greater beyond this point.

All these observations would seem to indicate a superior efficiency of the shallower Dearborn unit in contrast to Mr. Hubbell's conclusions that a slightly greater removal efficiency can be expected from the deeper tank. Admittedly, the writer has a disadvantage in the interpretation of the results through lack of detailed data on the investigation, but it does seem that on this basis the author's conclusions are not entirely reconcilable with the data presented. If the writer has not erred in interpretation and if Mr. Hubbell's conclusions are also correct, it then seems that other factors, due to variable conditions in the two units, have played an important part. One such factor which the writer has always considered of importance is the effect of ratios of length to depth on the efficiency of grit chambers. Theoretically, the chamber should be designed so that the value of $\frac{l}{v_h} = \frac{d}{v_s}$ for the smallest particle to be removed. This presupposes, however, that this and all larger particles will settle without turbulence and that the sweeping effect of unequal velocities is not to be present. In actual conditions, this quiescent state does not exist and any given size particle in the liquid is carried farther toward the outlet end of the tank. The distance to which larger sized particles are carried along the tank length is proportionally less, however, than any given decrease in the depth of the tank. The advantage of this fact is gained in a shallower tank. It seems to the writer that the results in Mr. Hubbell's paper also give evidence in this direction.

THOMAS R. CAMP,[7] M. AM. SOC. C. E. (by letter).—This paper describes an excellent experimental work on grit chambers. The author states in the "Synopsis" that his paper "is not a theoretical approach to the problem of sedimentation in flowing water, but rather a presentation of data in a practical and usable form heretofore not available to the sanitary engineer." These data have assisted the engineers of the Detroit project in preparing efficient designs for the grit chambers. The data are of even greater importance, however, in furnishing, for the first time, full-scale experimental checks of the validity of the rational theory of sedimentation of discrete particles in flowing water.

The Detroit engineers have previously used models successfully for studies of the flow distribution in the settling tanks of the Springwells water purification plant.[8] For this purpose model studies appear to produce reliable results. The conclusions reached by Mr. Hubbell, regarding the passage of oil and scum, however, seem questionable. In this case surface tension and viscosity probably come into play and neither is accounted for by the Froude model law. It is probably justifiable to conclude that if a draw-off velocity of 1.29 ft per sec in the model will remove scum, a somewhat higher velocity in the prototype will do likewise; but there seems to be little reason for concluding that the corresponding prototype velocity for scum removal is 5 ft per sec. In fact, it seems likely that grease will be removed at about the same velocity in both model and prototype since there is no method of reducing the scale of the grease.

Studies of the settling characteristics of suspended matter can be made better and more easily at full scale than with models. The particular difficulty in the use of models for this purpose arises in selecting and obtaining the proper size of material to settle in the model. The difficulty may be overcome in the case of discrete particles, but it is insurmountable with flocculent suspensions. In Equations (1), (2), and (3), the author attempts to show how the proper size of particle may be found for the model; but since Equation (1) is based upon the assumption that the settling velocity varies with some power of the particle size (an assumption which the author admits is incorrect) the method is rejected. This method of attack is much simplified and may be made correctly if the settling velocities are considered without regard to particle size. Settling velocities are readily measured by quiescent settling tests, but it is difficult to estimate them accurately from sieve analyses.

For both model and prototype the path of a settling particle will be the direction of the vector sum of its own settling velocity and the velocity of the liquid in which it is settling. If the velocity of the liquid is taken as the nominal or mean tank velocity, it follows from Equation (2) that the particle settling velocities should bear the same ratio as the tank velocities for equal removal. That is, the settling velocity for the model grit particles should be $\frac{1}{\sqrt{l}}$ times the settling velocity of the prototype grit. Since no quiescent settling tests were made for the Detroit grit, it is necessary to estimate the settling velocities from the particle size.

[7] Associate Prof. of San. Eng., Mass. Inst. Tech., Cambridge, Mass.

[8] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 344.

Fig. 12 shows the settling velocities of spheres with a specific gravity of 2.65 in water at 10° and 20° C. The values on the two curves are for the region beyond the range of validity of Stokes' law, and were computed from the curve of experimental values presented by Schiller[9] in terms of the Reynolds number. Fig. 12 also shows a curve for the settling velocity of sand at 18° C in terms of the grain size. It was estimated by the writer from experiments[10] of Richards, Hazen, and others. The position of this curve is only approximate, of course, and will vary with the shape of the particles. Very angular grains will settle at slower velocities, the retardation being greatest for the larger particles. For the critical grit size of 0.2 mm selected for Detroit, the corresponding settling velocity from Fig. 12 is about 2.3 cm per sec. The

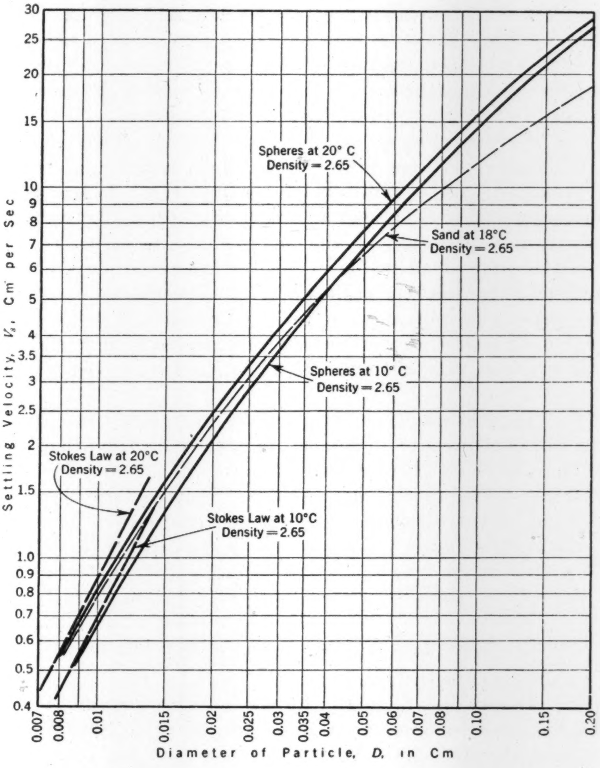

FIG. 12

[10] *Transactions*, Am. Inst. Mining Engrs., 1907, p. 283; also, *Transactions*, Am. Soc. C. E., Vol. LIII (December, 1904), p. 45.

proper settling velocity for the model, therefore, would be $\frac{2.3}{\sqrt{15}}$, or 0.6 cm per sec, which corresponds with a grain size of about 0.085 mm.

The author is incorrect in the statement that Stokes' law does not hold for particles settling in moving water. The settling velocity of a particle is a function only of the particle size, shape, and density, and of the viscosity and density of the fluid. When these are constant the settling velocity is constant both within the range of validity of Stokes' law and beyond. The settling velocity of a particle must be considered with relation to the surrounding fluid, however, and the direction and velocity of motion of a particle with relation to the tank correspond with the vector sum of the settling velocity and the velocity of the fluid with respect to the tank.

Theory of Sedimentation of Discrete Particles.—A simple theory[11] of the removal of discrete particles in continuous-flow, rectangular settling tanks has been presented by the writer which involves the following assumptions: (1) The direction of flow is horizontal, and both direction and velocity are the same in all parts of the tank; (2) the concentration of suspended particles of each size is the same at all points in the vertical plane perpendicular to the direction of flow at the inlet end of the tank; (3) all suspended particles maintain their size, shape, and individuality during settling, and the temperature of the fluid remains constant throughout the tank; hence, each particle is assumed to settle at constant velocity; and, (4) a particle is removed when it strikes the bottom.

In view of these assumptions, all particles settling at velocities such that their paths will be parallel to, or steeper than, the path from the liquid surface at the tank inlet to the bottom at the outlet end will be removed. The settling velocity corresponding to this path is known as the tank "overflow rate," and it is equal to the discharge per unit of surface area. The removal of particles which settle at any velocity less than the overflow rate is,

$$r = \frac{V}{V_0} = \frac{A\,V}{Q} \quad \text{.......................} (4)$$

in which r = the removal as a ratio; V_0 = the overflow rate = $\frac{Q}{A}$; Q = the discharge; and, A = the surface area of the tank.

Equation (4) was first presented by the late Allen Hazen,[12] M. Am. Soc. C. E., and represents sedimentation in a basin in which, according to Hazen, the water is absolutely quiet. For a continuous flow basin it represents the condition of no "vertical mixing" of suspended matter. According to Hazen, "in an actual settling basin the water is mixed more or less from top to bottom in the process, with the result that the sediment does not go down in the manner indicated by the assumption." The nearest approach to this "theoretical maximum" removal which may be obtained in an actual basin, according to Hazen's theory, is represented approximately by Curve C of Fig. 1 in Hazen's paper. For conditions which produce a removal of 100% as given by Equation (4), Hazen's Curve *C* gives only 66% removal. It has been previously shown by the writer[11] that, except for the proposition corresponding to Equation (4), Hazen's theory is fundamentally unsound. The effect of vertical currents upon the retardation of settling of grit is very much less than is indicated by Hazen's theory, as will be shown subsequently in comparing the results of the Detroit experiments with removals computed by means of Equation (4).

[11] *Transactions,* Am. Soc. C. E., Vol. 102 (1937), p. 306; and *Sewage Works Journal,* September, 1936, p. 742.

[12] "On Sedimentation," by Allen Hazen, *Transactions,* Am. Soc. C. E., Vol. LIII (December, 1904), p. 45 (see Curves *C* and *A*, Fig. 1).

In order to apply Equation (4) to a suspension of particles of varying settling velocity, it is necessary to have a "settling velocity analysis curve" analogous to a sieve analysis curve of sand. Such an analysis may be obtained by quiescent settling tests of the suspension. Lacking settling tests, the curve may be estimated for grit from the sieve analysis by means of Fig. 12. Curve 1 of Fig. 13 is prepared in this manner from the sieve analysis of the sand used in the experiment at Grand Rapids, Mich. As has been shown[11] previously, the total removel for a given overflow rate is,

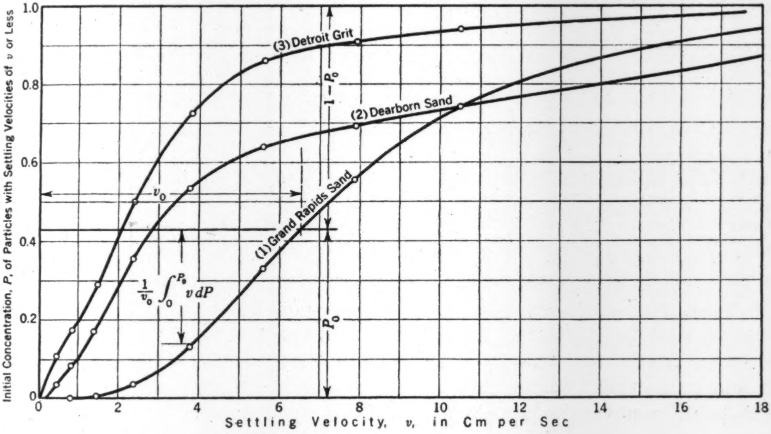

FIG. 13.—SETTLING VELOCITY ANALYSES

$$r = 1 - P_0 + \frac{1}{V_0}\int_0^{P_0} V\,dP \qquad (5)$$

in which P_0 = the value of P from the settling velocity analysis curve corresponding to V_0.

Curve 1, Fig. 13, indicates how this removal may be evaluated graphically from the settling-velocity analysis curve. The last term of Equation (5) is equal to the average vertical distance between the curve and the horizontal line for $P = P_0$.

Correlation of Theory with Results of Hubbell Experiments.—The "count and weigh" sizes of sand grains are normally 10 to 15% greater than the sizes of sieve openings. This is due to the grain shape, and the more the shape departs from the spherical the greater this discrepancy. On the other hand, the more the shape departs from the spherical the less the settling velocity will be. As the "count and weigh" size, and, hence, the grain shape, was not given for the Hubbell tests, the writer has assumed for an approximation that these two effects are balanced; and the grain size has been taken as the size of sieve opening.

Table 7(*a*) shows the results of computations for removal in the Grand Rapids grit chamber using Equation (5) and Curve 1, Fig. 13. The results show cumulative removals up to, and including, each section of the grit chamber in which the deposit was weighed in the Hubbell experiments. For comparison, the actual removals as measured by Hubbell (the ratios of the weights of deposited sand to the total weight of sand added) are also shown. The ratio of the actual removal to that computed by means of Equation (5) is shown under the caption, "Efficiency." Table 7(*b*) shows the comparison of the computed values for removal with the actual removal obtained in the Dearborn grit chamber. Curve 2, Fig. 13, gives the settling velocity analysis for this sand.

The sand used in the model of the Detroit grit chambers was quite uniform in size, being retained between 140-mesh and 150-mesh sieves. The writer has assumed a constant settling velocity for this sand which he has estimated from Fig. 12 at 0.85 cm per sec. The theoretical removal in the model is given by Equation (4) and is equal to $\frac{0.85}{V_0}$. The predicted removals in the Detroit grit chambers of sand 0.2 to 0.3 mm in size, based upon removals obtained in the model, are given in Table 3. Presumably these removals are the same as the actual values obtained in the model. Table 8 shows the removals computed by means of Equation (4) for the model compared with those shown in Table 3.

Table 9 shows the removals computed by means of the theory for the Detroit grit chambers compared with the removals estimated by Mr. Hubbell. Curve 3, Fig. 13, gives the settling velocity analysis for the assumed Detroit grit.

The correlation of the results obtained by the theory with those obtained in all three sets of experiments is very good for the entire length of the chamber, the discrepancy being less than 10 per cent. The errors are greatest for the shortest lengths considered, which may well be expected because of the difficulty of distributing both sand and water uniformly over the cross-section of the chamber at the inlet end and for other reasons which will be explained subsequently. The errors for the chambers complete, although small, are explainable in terms of factors not accounted for by the theory.

Factors Unaccounted for in Theory.—Reference to the assumptions made in the development of the theory will indicate that only one of the assumptions is fully met in the settling of sand; namely, that the particles do not coalesce in settling. Actual sewage grit contains a variety of substances other than sand, and some of the particles are mixed, or coated, with grease or organic matter. Some flocculation or coalescence in settling, therefore, probably does occur with sewage grit. Nevertheless, sewage grit is the only suspension commonly dealt with by sanitary engineers which approximates the assumption of no flocculation. It is the only suspension, therefore, which can be considered in terms of the foregoing theory. It is not possible to make a settling-velocity analysis of a flocculent suspension, because the particles are changing their settling velocities continuously.

The errors introduced by the assumption of uniform horizontal velocity in the chamber arise from two sources, short-circuiting and turbulence.

The effect of short-circuiting is to send some of the liquid through the chamber in less than the detention period and to retain some of it for longer periods. The overflow rate, therefore, is different for different portions of the contents of the chamber. A correction for this effect may be made if dye studies are available for the chamber provided, of course, that the velocity is great enough to maintain stable flow. The author presents results of dye studies for only the model grit chamber. These results are shown approximately by the writer in the form of a curve (see Fig. 14). Since the effect of short-circuiting is to reduce the removal given by the theory, and since the actual removal in the model was greater than that given by the theory, this curve cannot be used to explain the discrepancies for the model chamber.

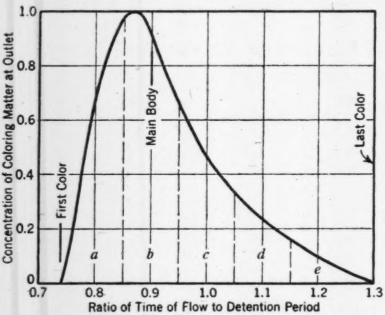

FIG. 14.—DYE CURVE TO SHOW SHORT CIRCUITY IN MODEL GRIT CHAMBER

The writer is at a loss to state precisely why the actual removal in the model exceeded the theoretical, whereas in both the Grand Rapids and Dearborn tests it was less than the theoretical. He suggests, however, that the manner of adding the sand at the inlet of the model might have been such as to carry much of it directly to the bottom. The second of the assumptions upon which the theory is premised may thus have been wide of the truth for the model and approximately true for both the Grand Rapids and Dearborn experiments. Since no measure of the accuracy of this assumption was made, this explanation must be regarded as hypothetical.

In order to explain the procedure to be used in correcting for short-circuiting, let it be assumed that the short-circuiting in the Dearborn chamber is also represented by Fig. 14 for the chamber as a whole. The time of settling of the suspension may be assumed equal to the time of passage of the dye through the chamber. The portion represented by *a*, Fig. 14, is approximately 26.6% of the whole, and it passed through the chamber in 81.5% of the detention period. The overflow rate for this portion is, therefore, $\frac{1}{0.815}$ times the average value of V_0 for the chamber, or 1.20 cm per sec. The corresponding removal from Curve 2, Fig. 13, is 94.8 per cent. These values are given in Table 10 with similar values for the other parts of the dye curve of Fig. 14. The weighted average removal corrected for short-circuiting is 95.8%, as compared with 96.2% without the correction. Hence, it may be concluded that the effect of short-circuiting is very small in a chamber in which the increase in removal is very small with increased length. This is particularly true if the short-circuiting is of as little magnitude as that represented by Fig. 14.

The effect of turbulence in retarding settling in the author's experiments should be examined for the full length of the chambers only, inasmuch as the deposit in any part of the chamber is influenced by transportation of sand along the bottom after it has settled. Transportation out of either the Grand Rapids or the Dearborn chamber could have occurred only if the material were held in suspension. It is reasonable to assume that most of the discrepancy between the actual removal in these two chambers and the removal given by the simple theory can be charged to transportation in suspension.

The phenomena of transportation of matter in suspension due to turbulence is just beginning to be understood. The recent developments in the theory of fluid turbulence in pipes make available much of value in the study of sedimentation. In turbulent flow, the shearing forces due to velocity gradients are accompanied by eddy currents. The magnitude of these eddies may be stated in terms of the "mixing length" and "mixing velocity." The effect of these eddies in retarding settlement is nil if the concentration of suspended matter is uniform throughout. If, however, there exists a concentration gradient, the effect of an eddy is to carry material from regions of higher concentration to regions of lower concentration in a manner precisely analogous to the process of diffusion. If, then, the concentration of grit in suspension is greater near the bottom of the chamber than above it, the effect of turbulence is to retard settling. If the concentration gradient with depth is just such that the downward motion due to settling is balanced by the upward motion due to turbulence the particles will be held in suspension indefinitely.

von Kármán, Ippen, and Rouse[13] have shown the application of the mechanics of fluid turbulence to the transportation of sediment in suspension, and have presented an equation for the concentration gradient at equilibrium in terms of the settling velocity of the particle and the so-called "friction velocity." Since the "friction velocity" may be stated in terms of the mean chamber velocity, this equation may be given in terms of the ratio of the particle settling velocity to the chamber velocity. Mr. Rouse also presents a diagram, first developed by Ippen, for the rapid solution of the equation.

The writer has examined this diagram for the grit-chamber experiments presented by Mr. Hubbell, in order to estimate what portion of the sand might be subject to permanent transportation in suspension if the grit chambers were long enough for equilibrium to be reached. The examination reveals that about 1% of the Grand Rapids sand, 32% of the Dearborn sand, and 35% of the Detroit grit (in chambers, 15 ft deep) are small enough to be subject to such suspension. This statement does not mean that the actual transportation in suspension will be anything like these values; because, for transportation to take place, the proper concentration gradient must exist before the particles settle out. The extension of the turbulent flow theory to cover the effect of turbulence in retarding settling before equilibrium has been reached has not yet been made.

---

[13] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), pp. 534–537.

The fourth assumption made in the development of the simple theory of sedimentation of discrete particles (namely, that a particle is removed when it strikes the bottom) is correct for a tank as a whole, provided the outlet is above the bottom. For a correlation of the Hubbell experiments with the theory, however, the assumption is not correct except for the whole chambers. Movement of particles along the bottom by traction, which was observed by the author to take place in at least one case, results in less deposit near the inlet and greater deposit near the outlet. The removal "efficiency" of the sections near the inlet for both the Grand Rapids and the Dearborn chambers, it will be noted, was less than that of the entire chamber. A part of this effect is doubtless due to "bed movement." Many studies have been made in recent years of the factors influencing stream-bed transportation, but the results thus far obtained are not sufficiently consistent to be used in predicting bed movement.

Conclusion.—A thorough understanding of the mechanism of settling of non-flocculent particles is essential before a rational approach can be made to the theory of settling of flocculent suspensions. The forces at work in the settling of discrete particles are also at work in the clarification of flocculent suspensions, but, in addition thereto, is the phenomenon of coalescence.

Data such as those presented by Mr. Hubbell are of great value in the development of the sedimentation theory. Many data have been collected upon the clarification of flocculent suspensions in full-scale settling tanks and in small pilot plants, but practically all these data are valueless in the development of the sedimentation theory because of the failure of the experimenters to measure all the variables. Most of the experiments that have been made, have had as their purpose the solution of particular sedimentation problems. The writer submits that if all the variables are measured in such experiments the particular problem may be solved with greater facility, and what is more important, the work will be of value to others. The ultimate goal is a theory which will enable engineers to design tanks intelligently from small-scale quiescent settling tests made upon the suspension to be clarified. In practically all experiments thus far made, settling characteristics, as distinct qualities of the suspensions, have not been measured. These qualities have been obscured by the characteristics of the basins in which the experiments have been run.

W. E. Howland,[14] Assoc. M. Am. Soc. C. E. (by letter).—The perfection of a technique for model testing of sedimentation basins is of great importance, and the studies reported in this paper should be of considerable value for this purpose.

In trying to account for the lack of agreement in results of the tests of percentage removal of fine sand obtained in the different models, several explanations may be given. The author suggests that the reduced turbulence in the smaller model (due presumably to a reduced Reynold's number and a nearer approach to the stream-line condition of flow) may account for the observed high percentage removal of the finer sand by this model. This may be a valid explanation notwithstanding the data presented by L. G. Straub,[15] Assoc. M. Am. Soc. C. E., which shows that the so-called (and mis-named) efficiency of sedimentation above a certain limiting value of the Reynold's number is independent of that function. This "efficiency" (defined as the ratio of the flowing-through time to the detention period probably first measured in sedimentation basins by C. H. Capen,[16] M. Am. Soc. C. E., in 1927), may be judged on theoretical grounds to have a doubtful effect upon the percentage removal of sediment in the basin—as has already been argued.[17]

---

[14] Associate Prof., San. Eng., School of Civ. Eng., Purdue Univ., La Fayette, Ind.

One other matter that deserves further emphasis is the so-called "transporting power of the stream." In a recent article,[18] Mr. W. M. Griffith considers this matter at length and gives a criterion for the silt transporting power of a given stream as $\frac{v}{d^{0.57}}$, in which v is the mean velocity and d the mean depth of the stream. Of course, one cannot be sure that this criterion is valid for the conditions met in a grit chamber since it was developed empirically for different conditions and it may not be at all applicable to a small scale model. Nevertheless, its consideration may throw some light upon the behavior of grit chambers. It would not be surprising to find some kind of an inverse relation between the percentage removal of sediment in a settling basin and the "transporting power" of the stream in the basin if, as in the case of these models, the values of $\frac{a}{t}$, as required by Hazen's theory of sedimentation,[19] are the same in all cases. (The letter symbol, a, is the mean time that a particle is in the basin, and t is the time theoretically required for the particle to settle from top to bottom of the basin.)

The following values of this function are determined for the various chambers considered in this study:

Prototype, $1 \div 16^{0.57} = 0.206$
Smallest scale model, $0.258 \div 1.067^{0.57} = 0.247$
Grand Rapids model, $0.9 \div 6^{0.57} = 0.324$
Dearborn model, $0.9 \div 3^{0.57} = 0.480$

It should be noted that no study has been made of the concentration of sand in the various tests. Without considering such effects these calculations indicate that the foregoing order of enumeration should also be the order of magnitude of the percentage removal of sediment in the basins. There is thus a certain measure of qualitative agreement between the foregoing statement and the observed percentage removal of sand in the model basins—the smallest model removed the greatest percentage of sand even when the sand used was half as large as in the larger models. Whether or not there is any value in this consideration the author can decide.

[19] "On Sedimentation," by the late Allen Hazen, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LIII, December, 1904, p. 45.

The writer would like to inquire if there are any data available showing the possible effect, if any, of the quantity of sand added upon the observed percentage removal for any given basin.

In conclusion, the writer would like to point to the value of running a similar test on the percentage removal of 0.2-mm sand in the prototype when built. Since the two sets of models used were designed on different principles, a final check on the prototype should help to answer such questions as these: Should sedimentation models, designed for identical values of $\frac{a}{t}$, have the same Froude number as the prototypes, or should, instead, the Reynold's number be made as nearly the same as possible as in the prototypes? Should the "transporting power," as defined herein, receive attention in the design of such models?

George E. Hubbell,[20] Assoc. M. Am. Soc. C. E. (by letter).—At this time the writer has little further to offer on the Detroit grit chamber model tests. Only tests of the finished structure itself will suitably close this discussion. However, there appears to have been some misunderstanding of the writer's conclusions. Professor Ridenour's interpretation of the data leads him to believe that shallow grit chambers are more efficient than deep ones. In Table 6, the comparison of removal on the basis of percentage of total sand is questionable since the actual pounds of the various sizes used in the two tests differ widely. Furthermore, it would appear that the critical size at which the $\frac{1}{V_h}$-ratio equals the $\frac{d}{V_s}$-ratio is best indicated by the size of sand that is completely removed. For the Grand Rapids test, this is 0.295 mm to 0.417 mm; and for Dearborn it is 0.2 mm, the Dearborn $\frac{L}{d}$-ratio equaling 29.8. The equivalent length for Grand Rapids, therefore, would be 179 ft, and the tests indicate a critical size of 0.2 mm, as would be expected if the relationship $\frac{1}{V_n} = \frac{d}{V_s}$ is substantially correct. With regard to the average size of sand removed in the equivalent section of the two chambers, the different character of the sands involved should be considered, the Grand Rapids test sand having an over-all average size of 0.57 mm as compared to 0.42 mm for the Dearborn sand. The writer does not conclude that slightly greater removal efficiency can be expected from the deeper tank, but rather that the same degree of efficiency can be obtained with deep chambers properly proportioned.

Professor Camp has developed, in a masterly manner, the theoretical grit-chamber efficiency to be expected, based on the laws governing sedimentation in quiescent water, and has shown that the efficiencies actually obtained in the Grand Rapids, Dearborn, and model tests, and estimated for the Detroit grit chamber, all in flowing water, are about 10% less than those theoretically expected. These results appear to indicate a reasonably approximate measure of the effects of cross currents and unequal distribution of velocities which prevail in grit chambers under the usual operating conditions. It was assumed arbitrarily that a prototype velocity of 5 ft per sec would remove scum and grease, and no conclusion was reached from the model test other than that, if 1.29 ft per sec were adequate in the model, the higher velocity would be adequate in the prototype.

---

[20] Cons. Engr. (Hubbell, Roth & Clark, Inc.), Detroit, Mich.

Professor Howland has raised some interesting questions with regard to the relationship between the transporting power of flowing water and grit-chamber design. Considerable information on the transporting power of streams is available, but it is difficult to apply it directly to grit-chamber design. The average velocity in the model was 0.26 ft per sec, and the sand used had a diameter of approximately 0.1 mm. Competent velocity computations would tend to indicate that sand of this size is critical and would be transported. Referring to the prototype, it would appear from similar computations that a sand, for example, of 0.35 mm would not settle at a velocity of 1.0 ft per sec since the competent velocity for such a particle size is variously estimated at from 0.5 to 0.7 ft per sec. Furthermore, the writer believes that any general expression that does not take cognizance of particle size is, of necessity, limited in usefulness, because there can be no question that, with reference to sedimentation, settling velocities, particle sizes, and tank velocities are intimately related. In so far as the writer knows, no data are available on the effect of concentration on removals.

STRUCTURAL BEHAVIOR OF BATTLE-DECK FLOOR SYSTEMS

BY INGE LYSE,[1] M. AM. SOC. C. E., AND INGVALD E. MADSEN,[2]
JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. H. N. HILL AND R. L. MOORE, JONATHAN JONES, AND INGE LYSE AND INGVALD E. MADSEN.

SYNOPSIS

Results of two years of investigating the behavior of battle-deck flooring are reported in this paper. Four one-third sized models and one full-sized floor panel, designed on the basis of the results obtained on the preliminary models, were tested under the action of a concentrated wheel load, such as the specifications recommended for H-20 loading. The battle-deck flooring acted as an integral unit distributing the wheel load over various stringers, with the amount of load taken by the several stringers depending on their spacing. The plate acted with the stringer so as to form a T-beam which, if taken into account in the design, might result in an economy of 10 to 15 per cent. The width of plate contributing to the T-beam action was also found to depend on the stringer spacing. When the stringers were coped in on the floor-beams, partial fixation resulted with further economy in design. The models were loaded with dead weights, and the full-sized floor panel was tested by means of a jack and spring device. The test results gave a basis on which to formulate a rational design method for battle-deck floor systems.

INTRODUCTION

Experiments were made on four one-third sized models, based on a prototype bridge floor consisting of two panels 20 ft long and 10 ft wide. The first model represented a floor with a $\frac{3}{8}$-in. plate on stringers, spaced at 24 in. The tests showed that such a floor was not capable of supporting an H-20 loading. Consequently, the second model had stringers welded between those of the first model, making the prototype a floor with a $\frac{3}{8}$-in. plate on stringers, spaced

---

NOTE.—Published in January, 1938, *Proceedings*.

[2] Associate in Civ. Eng., Dept. of Civ. Eng., Columbia Univ., New York, N. Y.

12 in., center to center. This model proved adequate in supporting the load, and the next step was to determine the more economical design. Comparative cost data indicated that although a widening of the stringer spacing might increase the weight of the floor slightly, the decrease in welding cost would more than offset the gain in weight. Thus, for the third floor model, a prototype was selected which consisted of a $\frac{3}{4}$-in. plate laid on stringers spaced at 30 in., and for the fourth model, a $\frac{9}{16}$-in. plate on stringers spaced at 24 in.

The results of the model tests showed that the floors behaved according to certain relationships. Design methods and procedure, as established from these results, served for the construction of the full-sized floor panel. The agreement between the design stresses and the measured stresses in this full-sized floor indicated a check on the design assumptions. The full-sized floor consisted of 12-in. standard I-beams, spaced on 26-in. centers, with a $\frac{11}{16}$-in. plate. The floor was 16 ft 9 in. in span and 9 ft 5 in. wide. This span length was adopted because the full-sized panel was tested as a simple beam with the stringers resting on the floor-beams, representing the distance between the points of contra-flexure of a 20-ft panel length with the stringers in the bridge floor coped into the beams.

THE PROBLEM

The problem of determining the behavior of battle-deck flooring may be divided broadly into two parts: (1) The stresses in the plate; and (2) the action of the stringer; that is, the amount of load carried by each stringer and the interaction of plate and stringers in resisting flexural stresses. The investigation was limited to the study of these conditions in relation to battle-deck flooring for highway bridges subjected to concentrated loads. For an adequate solution of the problem it was necessary to determine:

(*a*) The strength and deflection of battle-deck flooring under concentrated loads;

(*b*) The properties of the floor-plate in distributing the load over various stringers;

(*c*) The width of plate acting with the stringers as the compression flange of a T-beam;

(*d*) The length of plate under concentrated load affected by the load;

(*e*) The effect of changing the distance between the stringers;

(*f*) The degree of fixation at the ends of the stringers; and,

(*g*) The degree of fixation at the ends of the plate.

Little work has been done in this field, although some mathematical studies have been made on the width of plate acting in a T-beam under various loading conditions.[3] Even less is known of the distribution of load among the various stringers of the floor. For uniform loads over a floor, simple relationships obtain, but for concentrated wheel loads such as were used in this investigation, the problem becomes very difficult.

What actually happens to a stringer floor under load is readily visualized, but a strictly mathematical analysis is practically impossible because the floor is statically indeterminate to a high degree. As the load is applied the stringer beneath it deflects and the plate deflects with it, acting as a beam to transmit shear to the next stringer. This second stringer will also deflect and carry on the distribution. Theoretically, the distribution will go to all the stringers, although, practically, the effect may become so small after being distributed over three or four of them that any further distribution may be neglected. This action is quite different from that usually assumed in design, namely, that the load is spread equally over a certain definite number of stringers. Since the deflection of a beam varies as the cube of the span (that is, the spacing between the stringers) and inversely as the cube of its thickness, a floor with equal spacings between the stringers has a constant proportion of the shear transmitted between each stringer. In other words, the load on a floor is distributed throughout the floor in a geometrical ratio.

---

[3] "Die Mittragende Breite," by Theodor von Kármán, M. Am. Soc. C. E., in Beiträge zur Technischen Mechanik und Technischen Physik, August Föppl Festschrift, Berlin, 1924.

The action of the plate under a concentrated load cannot be determined readily. The plate may be regarded as a rectangular plate supported along the edges, but the behavior is complicated by the fact that the deflection of the stringers varies along the plate, giving it an elastic support; and, in addition, the rotation of the stringers makes the degree of fixation in the plate an uncertain quantity.

In this investigation strain readings were taken before and after loading to determine the stresses. Slope readings were also taken along the stringers before and after loading. These readings were plotted, and the resulting curves were differentiated once to obtain the moments, and then a second time to obtain the shears. They were also integrated to obtain the deflections, and the deflections were measured directly for a check. From mechanics, the slope curve, differentiated twice, and multiplied by $E\,I$, gives the shear. Since the sums of all the shears of the stringers must be equal to the applied load, the value of the moment of inertia, I, was selected so that this became true for the experimental results. Knowing the value of I, it was easy to determine how much plate was acting with the stringer as a T-beam. The values of the shears on each stringer indicated how much load was carried by the various stringers. Furthermore, when the T-beam action of the stringer was known, the section modulus could be computed, and the stress could be determined from the moment curves which had been computed. These stresses were compared with the measured stresses, and their agreement served as a check on the work. The stresses in the plate were determined by means of Huggenberger tensometers.

PROGRAM

The four models were tested with the dead loads in various positions. In what is called a typical run, strain readings were taken along, and transversely between, the stringers, and level-bar readings were taken along the stringers both before and after the load was applied. The difference between the initial and final readings was the effect due to the applied load. The strain, multiplied by the modulus of elasticity, gave the stress at any point in the stringer; and the difference in the level-bar readings gave the slope due to the applied load. Such tests were made on the models with the load in all parts of the floor. However, the load in the middle of the stringer caused the larger stresses and, therefore, governed the design. In the full-sized panel, tests were made only with the load in the middle of the floor.

For these tests, the sum of all the slope readings along a stringer at any point would give the deflection of the stringer at that point. However, this was supplemented by tests in which Ames dials were placed along the stringers to measure the actual deflections. These results agreed quite closely with the integration of the slope readings and served as a check on them.

The plate stresses were obtained by measuring the strains in the plate with the tensometers. The load was placed in various parts of the plate, and tensometers were located at all points where any effect was noticed, thus recording the distribution of the plate stresses. In making some of the models, strain measurements were also taken on the stringers before and after welding to furnish an idea as to the severity and the effect of the welding stresses.

TESTING

The models were made of standard rolled-steel sections and plate. They were constructed on the basis that the model should be one-third size. However, since the prototype could not be reduced in all proportions without expensive machining, the stringers were machined so as to keep the clear spans of the plate in proportion, and they were designed so that the stresses in the model would be approximately the same as in the prototype. The ideal could not quite be attained since the smallest I-beams rolled gave about a 25% excess over the computed section modulus. The panels in the model were 80 in. by 40 in. The first two models consisted of two panels welded together. The last two models consisted of only one panel each, but they were welded in the same frame and their floor-beams consisted of channels. After the

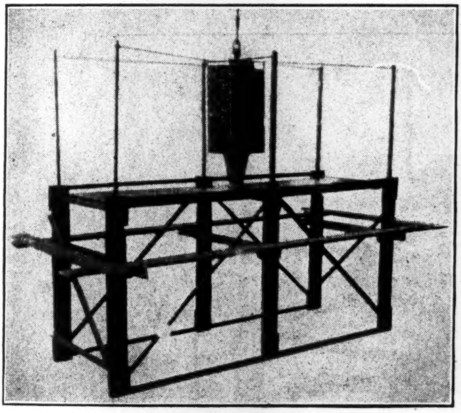

FIG. 1.—FLOOR MODEL AND LOAD

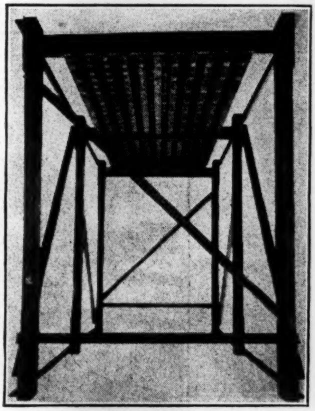

FIG. 2.—BOTTOM VIEW OF SECOND FLOOR MODEL

testing of the last two models was completed, a filler plate was inserted between the two adjacent channels, and weld metal was deposited so as to make an I-beam and cause the panels to be continuous. A view of the first two models is shown in Figs. 1 and 2. All the models had the same type of stringers, but the stringer spacing and the plate thickness varied. The plate in the first two models was steel metal sheeting of a low strength and yield point. This type was selected because the uniformity of thickness which sheeting possesses was an important factor in the $\frac{1}{8}$-in. plate thickness used in these models. The $\frac{1}{4}$-in. and $\frac{3}{16}$-in. plates in the third and fourth models were of the regular structural grade of steel and passed the specifications.

Great care was necessary in welding the models in order to avoid warping, particularly in the first two where the plate was so thin. They were fabricated by first tacking the stringers on to the plate, after which the weld metal was deposited, alternating from one spot to another on the floor so as to minimize the heat and thus decrease the tendency to warp.

The models were loaded by a dead-weight loading rig which is shown in Fig. 1. The Bureau of Public Roads, United States Department of Agriculture, has approved[4] a loading area of 20 in. by 10 in. for the rear wheel of an H-20 loading. This assumes a tire 20 in. wide, with a pressure of 112 lb per sq in., giving 10 in. of longitudinal bearing.

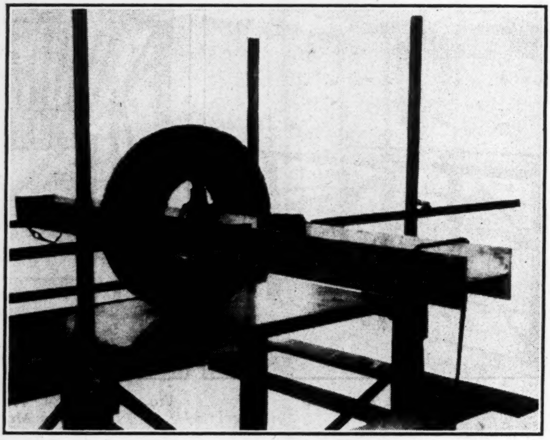

FIG. 3.—TIRE LOADING RIG

The loading rig consisted of a cast-iron block to which a frame was fastened to carry the additional dead weight. The initial weight of the rig was 400 lb. The load was applied, in 50-lb increments, through a steel bearing plate which was one-third size, or $6\frac{2}{3}$ in. by $3\frac{1}{3}$ in. A piece of soft rubber, $1\frac{1}{2}$ in. thick, was placed under the bearing plate to keep the load constantly uniform as the plate deflected, and a piece of cellotex was placed under the rubber to keep the area in contact with the plate constant.

---

[4] Specifications for Highway Bridges, Am. Assoc. of State Highway Officials, 1935, p. 173.

A load of 2 489 lb should cause the same stresses in the model as would the rear wheel of an H-20 truck in the full-sized panel. A load of 2 500 lb was used in the model tests.

To show that the loading rig gave a uniform load distribution on the plate, and to compare its action with that of a tire, comparative load tests were made. The floor was tested by means of the loading rig, and strain measurements were taken around the load at a number of critical points. Then the floor was tested by means of a tire, as shown in Fig. 3. The results of these tests were compared and found to be equal within the limits of experimental error, showing that the loading rig gave essentially the same results as an actual wheel load.

FIG. 4.—FULL-SIZED FLOOR

No trouble was experienced with warping in the full-sized floor panel, due to welding, so that it was unnecessary to adopt any special welding procedure. The plate was so thick that it dissipated the heat rather quickly. The structural grade of steel was used in the floor.

The floor was set in a frame as shown in Fig. 4. It was tested by jacks such as that shown in Fig. 5, the load being measured by the deflection of calibrated springs. It was possible to ascertain the load on the floor by this method to within 1 per cent. In order that the pressure on the floor be kept uniform as the plate deflected, the deflection of the plank on which the spring set-up was placed, was computed, and the plank was made of such a thickness that its deflection would be approximately equal to that of the plate. The deflection of the plank was computed on the basis of a beam on a yielding foundation under uniform pressure.

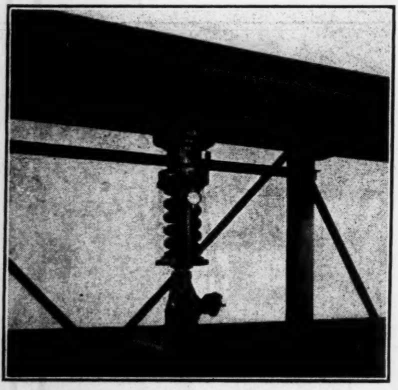

FIG. 5.—JACK USED ON FULL-SIZED FLOOR

The models were held in a frame consisting of vertical posts made of 8-in. channels braced with angles (see Figs. 1 and 2). The floor-beams of the models were welded to the vertical channels to simulate the connections of beams to hangers in an actual bridge construction. The full-sized panel was held in a truss made of beams and angles, the details of which are shown in Fig. 4.

The strains in the stringers were measured by a fulcrum-type Whittemore strain-gage, equipped with a 0.0001-in. Ames dial. It is accurate to about 600 lb per sq in., as a tolerance of 0.0002 was allowed in repeating a reading. Since temperature changes cause strains in a structure that would be measured by the gage, the observations were made when these changes were at a minimum. Usually, therefore, temperature could be neglected, but when variations occurred, corrections were applied to the strains from observations on mild steel standards.

The tensometers which were used in the plate tests had gage lengths of 1 in. and 0.5 in. They were accurate to within about 500 lb per sq in., depending on the gage length.

Two level-bars were used. The one in the model tests had gage lengths varying from 1 in. to 6 in. However, the 5-in. gage was used almost entirely. It was fitted with a very sensitive bubble so that readings could be repeated to 0.0001 in., if the point hit the same spot on the floor. Hitting the exact spot was practically impossible, and, therefore, the accuracy was limited by the irregularities in the plate surface. For the full-sized model, the bubble was mounted so that the level-bar had a 15-in. gage length. This would make the instrument three times more accurate than it was on the 5-in. gage length, but in this case, again, the accuracy was limited by the irregularities in the plate surface. These irregularities were worse in the full-sized plate than in the models. In all cases the spots where the micrometer point of the level-bar rested were ground smooth and polished with an emery cloth.

TEST DATA AND RELATIONSHIPS

Many tests were made on all the models and on the full-sized panel. It is impossible to describe all these tests, however, and only the results of the significant and important runs will be given.

Tests on First Model of 24-Inch Stringer Spacing.—A series of nine runs was made on the first model. Some of the load positions included the quarter-points of the stringers, the center of the span, and the points adjacent to the floor-beams. As far as stringer stresses are concerned, the load in the center of the span caused the critical stresses.

In Series 16 (see Fig. 6), the load was placed between Stringers *E* and *G*, in the middle of the first panel. The results of the tests are shown in Tables 1 and 2. The two adjacent stringers, *E* and *G*, received 80% of the load, whereas Stringers *C* and *I* received about 10 per cent. The stringers that were away from the direct influence of the load carried over about 25% of their load to the adjacent stringer. The beams acted as if they were partly fixed, the average fixation factor on the left being about 15% and that on the right about 39 per cent. Due to this fact, the shear on the left was less than that on the right. These fixation factors were the ratios of the moments at the supports to those of a fixed-end beam.

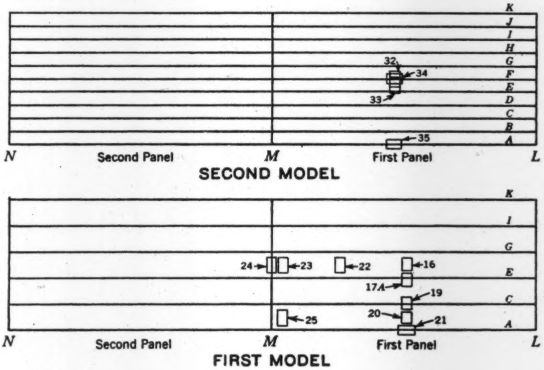

FIG. 6.—LOADING POSITIONS FOR FIRST AND SECOND MODELS

In order that the shears should equal the applied load, the moment of inertia of a stringer had to be 3.54 in.^{4}. This required 5.50 in. of plate acting in the compression flange. With these values the computed center moment was found from the slope curves, and the fiber stresses were computed. The measured stresses did not agree with those computed as well as expected, and the reason for this will be discussed subsequently.

The center deflection was computed from the formula:

$$y = \frac{W L^3}{192 E I} (-4 + 2 F_l + F_r) \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

The deflection was obtained by adding the areas under the slope curve. The agreement between the observed and measured deflections served as a check on the accuracy of the differentiation and the computations.

In Table 1(*b*) are shown the results of Series 17A on the first model. In this run, the load was placed directly on Stringer *E* (see Fig. 6), at its center. However, the loading area was so wide that the bearing block overlapped the plate and some of the load was transferred directly through the plate to Stringers *C* and *G*. The ratio between the shear carried from one stringer to another

in the direction away from the load is 0.24. The average value of F_l was 23% and that of F_r, 35 per cent. The value required for the moment of inertia of the stringers to make the shear equal to the load was 3.35 in.^{4} for the interior stringers, and 2.84 in.^{4} for the exterior stringer, *A* (see Table 2). These values for *I* were developed as follows: First, the shears were computed using a value of *I* corresponding to full T-beam action; that is, using 8 in. of plate for the top part of the T in the interior stringers, and 4 in. for the exterior stringers. This made the value of the shears too large. Next, the values for the moment of inertia were multiplied by a factor so that the shears would equal the load,

and then the width of plate required for this value of the moment of inertia was computed.

The left reactions were again found to be less than the right, as would be expected, since the left fixation factor, F_l, was the smaller. It is seen that Stringer *E*, directly beneath the load, received fully 50% of the load.

In Series 19, the load was placed on Stringer *C*, which was next to the exterior stringer. Consequently, the load could not be distributed so widely. In this case, the loaded Stringer *C* carried 55% of the load, or 5% more than in the former series.

The worst loading condition for the floor occurred in Series 21, Table 1(*c*), when the load was placed directly over Stringer *A*, which thus received 65% of the load. However, this loading would not be attained in an actual bridge, since, in order to place the wheel directly over an exterior stringer, a considerable part of the wheel would project beyond the floor. When the load was placed as close to the exterior stringer as is practical, it took about 50% of the load, and its design would be about the same as that of an interior stringer.

Referring to the stringer stresses of Series 21, the measured stress gave values that would require much more plate in T-beam action than the total plate width between stringers. This shows that there were other stresses in the stringer besides those due to bending. The observed slopes of Stringer *A* during this test are shown in Fig. 7(*a*), and the corresponding stresses in Fig. 7(*b*).

The results of quarter-point loading on the floor were quite interesting. The length of plate in T-beam action was the same as that in the corresponding center of span loadings, but the shear transferred from one stringer to another was only 0.08 of the shear in the stringer, instead of the 0.25 which occurred in the former cases. This agrees with the fact that the shear transferred from one stringer to another depends on their relative deflection; and since the stringers deflected less at the quarter-point, the difference in deflection between two adjacent stringers was less. Carried to the extreme, when the load is at the end of the stringer, one stringer will take all the load and must be designed for it.

Supplementary tests were also made on this model. In Fig. 8 the deflection of Stringer *E* is plotted against the load, which was placed in a position corresponding to Series 16. It is seen that the load-deflection relation is a straight line (as would be expected), showing that the width of plate acting as a T-beam was constant and did not vary with the load. The center deflection diagram for the plate is also given in Fig. 8. The curve slopes upward to the left showing that the load required for equal increments of deflection increased with the increase in the load on the plate. In other words, catenary action helped to support the plate.

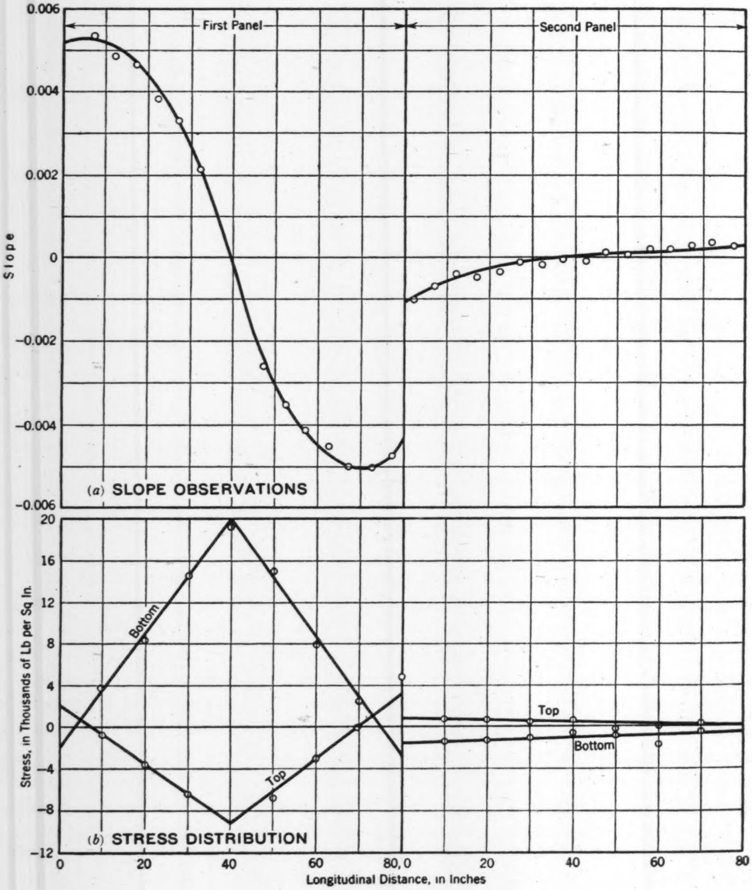

FIG. 7.—TESTS OF STRINGERS *A*

In Fig. 9, the deflections of the plate and Stringer *E* are plotted against the longitudinal axis of the stringer for a 2 500-lb load. The deflection curves for quarter-point loading are also given. In the stringers, there is a slight initial reverse curvature of the deflection curve at the ends of the span. This shows a slight degree of fixation. The curve for the plate, in sharp contrast to that of the stringers, slopes gradually and then changes quite sharply beneath the load.

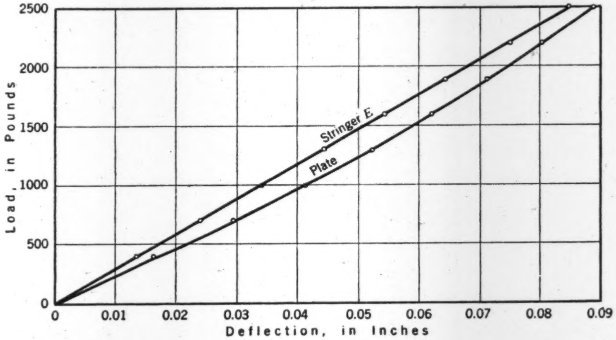

FIG. 8.—LOAD-DEFLECTION RELATIONS FOR CENTER STRINGER AND PLATE

In all these tests the stringers rotated considerably. However, the top of the stringer showed little or no rotation, which indicated that the stringers must have rotated about the plate. This rotation is at least partly due to the deflection of the floor plate. Evidently, the stringers were subjected to torsional forces and thus contributed to the load distribution.

Tests on Second Model of 12-Inch Stringer Spacing.—The second model was the same as the first, except that the stringers were spaced 4 in., center to center, instead of the former 8 in. The results were similar to those of the first test, but due to the decreased stringer spacing, the floor was stiffer so that the load was distributed over more stringers.

The results of Series 32 (see Fig. 6), in which the load was placed directly on top of Stringer *F*, are shown in Table 1(*d*). The width of the loaded area was so great, relatively, to the stringer spacing that when Stringer *F* was loaded, the area overlapped on the two other stringers, *E* and *G*. Full T-beam action was present in this series. Stringer *F* took the largest proportion of the load—about 30 per cent. The ratio of shear carried from one stringer to another, in the direction away from the load, was about 0.43, instead of the 0.25 found in the first model. The average fixation factor was about 12% at the left (F_l) and about 35% at the right (F_r).

The center moment, stress, and deflection were computed for the second model in the same manner as for the first. The slope readings checked the deflection. However, the ratios between the various stringers did not stay quite as constant for the shear, moment, and deflections, as they did in the first model. This shows that the slope curves were not exact second-degree curves, although they were so assumed, and, consequently, a slight error occurred in the differentiation and integration. The load on the other sections of the floor gave results similar in nature to those shown for Series 32.

After the regular runs had been made on the second model an attempt was made to test it to destruction. It was loaded by means of a 20-in. I-beam extended out as a cantilever from an 800 000-lb testing machine. It was first loaded to 15 710 lb, which is more than six times the design load, at which time the deflection under the load was 0.531 in. The load was released to 4 700 lb and the deflection was 0.240 in., of which 0.118 in. was permanent set.

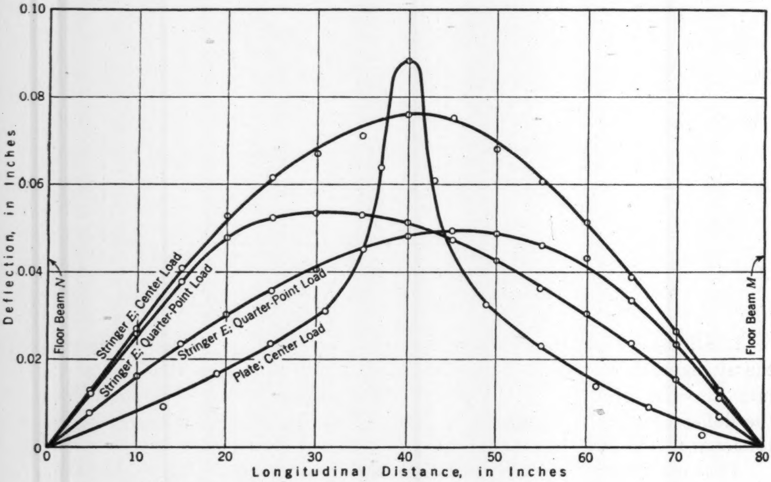

FIG. 9.—LOAD-DEFLECTION RELATIONS FOR STRINGER *E* AND PLATE

The model was loaded again to 28 510 lb, when the testing had to be discontinued due to the incipient yielding of the loading beam and the bowing of the vertical legs of the frame holding the floor. At this load, the total deflection was about 1 in. The stringer under the load had yielded and thrown much of the load on to the two adjacent stringers, which were also beginning to yield. Upon removal of the load, a permanent set of about 0.5 in. was observed.

There was no sign of yielding in the plate, and the only sign of failure was a scaling of the whitewash in one of the welds holding the floor-beam in the supporting frame.

Tests on Third Model of 30-Inch Stringer Spacing.—The third model was based on a prototype with a $\frac{3}{4}$-in. plate welded to stringers spaced on 30-in. centers. This model, as well as the fourth, consisted of only one span, and since the stringers were coped into the floor-beams there was a partial degree of fixation. In these models, the plate was extended to the center of the exterior stringer, *A*, whereas it overlapped 2 in. from the center of the exterior stringer, *E*. This was done to see whether the overlapping plate was efficient in T-beam action.

The results of the tests on the third model were very similar to those of the first two. The results of the case in which the load was placed on top of Stringer *C* are given in Table 1(*e*). Stringer *C* took 59.4% of the load, which is a greater proportion than in the first two models. This was due to the greater stringer spacing. For a similar reason the width of plate in T-beam action was not as large as in the first two models. The fixation factor for the loaded stringer was small, as would be expected. For the other stringers the value of *F* is negative, denoting an applied moment at the end of the stringer. The reason it is negative is that, due to the partial fixation of the loaded stringer, the floor-beam rotates and imposes applied moments on the adjacent stringers.

A number of tests were made in a study of the plate stresses in the third and fourth models. Similar tests were made on the full-sized floor and since these were more complete and gave essentially the same results as those on the models, only the results on the full-sized floor plate are given in this paper. Full T-beam action was not present in these models. Accordingly, the compression in the top part of the T-beam would be expected to decrease away from the stringer. This decrease was found to be linear, as shown in Fig. 10, for the variation of the compression in the plate between Stringers *C* and *D* when the load was placed between them.

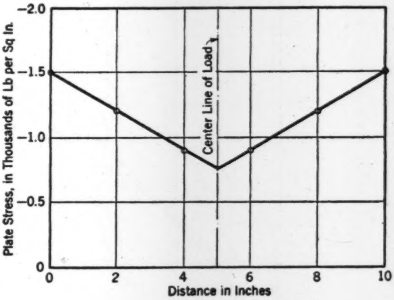

FIG. 10.—STRESS DISTRIBUTION IN FLOOR PLATE WHEN LOAD IS PLACED BETWEEN STRINGERS *C* AND *D*

Cross-bracing was welded between the stringers in one of the bays of this model. It consisted of $\frac{1}{4}$-in. by 2-in. plates welded to the stringers and the plate, at 12-in. intervals. Although the secondary bracing was spaced this closely, the plate stresses were reduced very little.

Tests on Fourth Model of 24-Inch Stringer Spacing.—The fourth model was based on a prototype with a $\frac{9}{16}$-in. plate welded to stringers at 24-in. centers. In this model, an attempt was made to evaluate the welding stresses. Strain readings were taken on the stringers and on the part of the plate over the stringers, before and after the floor was welded together. The welding stresses were greatest in the plate because most of the welding was done there. The longitudinal welding stresses in the plate varied from about 4 000 lb per sq in. over the exterior, to 9 000 lb per sq in. compression over the interior, stringers. The stress along the bottom of the stringers was about 2 000 lb per sq in. in tension. The transverse welding stress in the plate between the stringers varied from 15 000 lb per sq in. to 20 000 lb per sq in. in compression. These stresses did not seem to affect the test results.

The results of the various tests of the fourth model were similar to those of the previous models. Table 1(*f*) gives the results for the case in which Stringer *C* was loaded. This stringer is seen to take 48% of the load.

After the regular runs had been made on the third and fourth models, they were welded together to form a two-panel floor. A run was taken similar to that in the third model for which the results are given in Table 1(*e*), and the results for the two-panel model were very similar to those for the third model except that the fixation factor at the intermediate floor-beam was increased to 50 per cent. The stresses and deflections in the floor-beams were found to be smaller in accordance with the increased fixation factor.

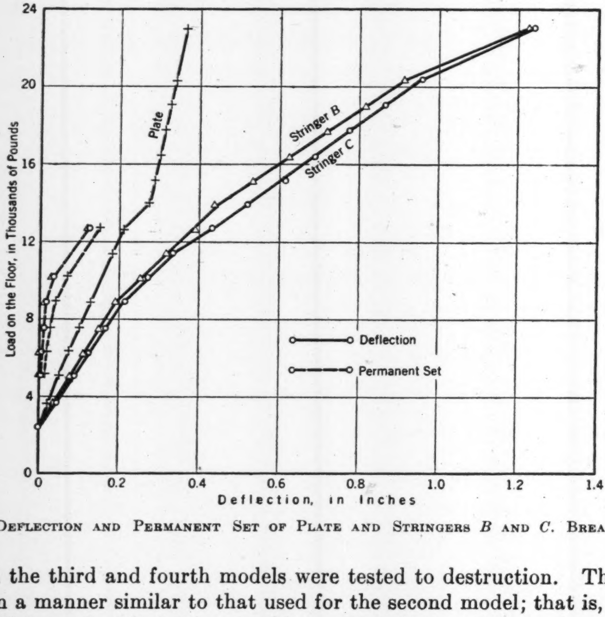

FIG. 11.—DEFLECTION AND PERMANENT SET OF PLATE AND STRINGERS *B* AND *C*. BREAKING TEST

Both the third and fourth models were tested to destruction. They were loaded in a manner similar to that used for the second model; that is, a cantilever load from the big testing machine. The third model was loaded up to 26 744 lb and the fourth, to 27 911 lb. In each case, the testing had to be discontinued due to incipient yielding of the loading beam. At these maximum loads, which were about eleven times the design load, large deflections were present although nothing broke. The large reserve strength is due to the fact that as one stringer yields, the increase in load is taken by the adjacent stringers while the original stringer still holds its yield-point load. This process continues until all stringers have yielded.

In the third model the load was placed on the plate between Stringers *B* and *C* (Fig. 6). Fig. 11 shows a diagram of the load-deflection and permanent-set curves of the stringers and the plate. At the maximum load, the deflection was 2 in. and the permanent set was 1 in.

The fourth model was tested with the load directly over Stringer *C*. The results were about the same as for the third model. A diagram of the deflection of the centers of the stringers under various load increments is shown in Fig. 12.

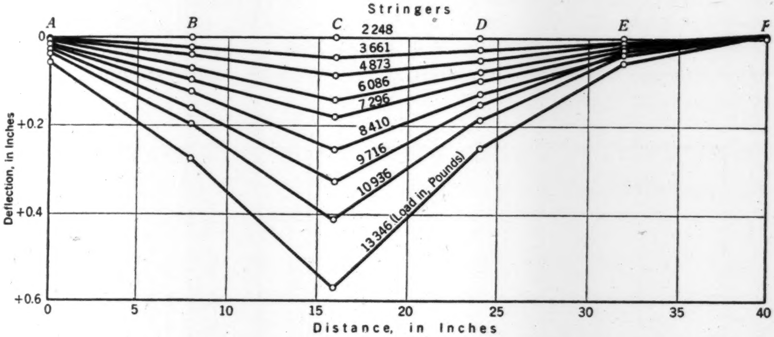

FIG. 12.—DEFLECTION CURVES FOR CENTER OF STRINGERS. BREAKING TEST, MODEL NO. 4

Tests of Full-Sized Floor Panel.—The full-sized floor panel was built according to a design procedure, determined by a study of the results of the model tests. The panel was 16.75 ft long, center to center bearing, and 9.42 ft wide. This floor was built so that it would act as a test on the design procedure, and serve as a check on the model tests. How well it did this is illustrated in the comparison of the design values with the measured values of stress and deflection for the critical sections of the floor, shown in Table 3. The check is very good considering that the properties of structural sections may vary as much as 5 per cent. The tests on this full-sized floor were similar to those of the models. Table 3 gives the results when the load was on top of Stringer *C*.

Measured value...	26 000	0.111	13 900	0.170	56	17.5	...

Because of the large dimensions of the full-sized floor, it was possible to obtain more data concerning the stresses in the plate than had been possible in the models. A large number of tensometer readings were taken in order to obtain the stress distribution in the plate. Fig. 13(*a*) shows the distribution of the transverse stress in the plate along the length of the floor. This stress is the greatest in the plate, since it lies along the short span between the stringers. It is seen to have a peak of 26 000 lb per sq in. at the center of the load, rapidly decreasing asymptotically along the plate. The compression in the top of the plate is seen to be similar to the tension in the bottom. Complete readings could not be obtained for the compression side since the load was in the way. The distribution of the transverse stress in the bottom of the plate, across the width of the floor, is shown in Fig. 13(*b*). In the loaded span, the stress in the plate was zero at the edges of the stringer flanges. The stress changed to compression along the flange, and rapidly dropped to zero at the next stringer.

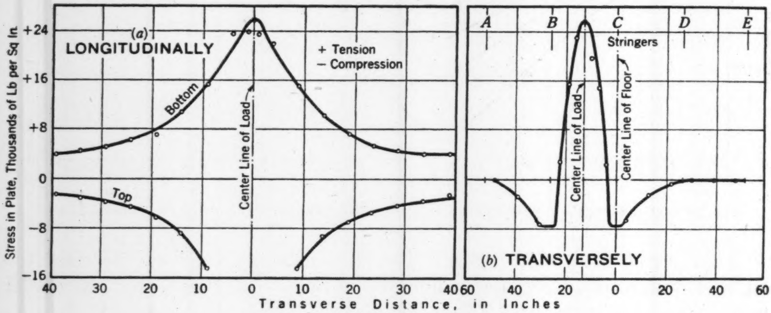

FIG. 13.—TRANSVERSE STRESS IN PLATE OF FULL-SIZED FLOOR

An over-load test was made on the full-sized floor. It was loaded up to 56 000 lb, or two and one-half times the design load. The deflection of the floor increased linearly with the increase in load. At a 50% over-load, there was an over-all permanent set under the plate of 0.005 in. At the maximum load of two and one-half times the design load the permanent set was 0.025 in. No signs of failure or yielding could be determined with the exception of a scaling of the whitewash near one of the welds, between the plate and the stringer. After the load was removed, the floor appeared just as perfect as ever, and one could never have detected by eye that it had been overloaded. The maximum deflection of the plate had been 0.269 in.

DISCUSSION OF RESULTS

The results of these tests show that the battle-deck floors acted as an integral unit. The load was distributed from one stringer to another by means of the plate, which acted as a cantilever beam, in proportion to the relative deflection of the stringers. This distribution factor was a constant for a definite stringer spacing and plate thickness. In all cases, as shown by the tables, the carry-over factor was larger for the stringers close to the load than for those away from the load. Considering the case in which the load was directly over one stringer, the adjacent stringers took, not only the load carried over by their relative deflections, but also some of the load itself, as the wheel load was so wide that it overlapped the loaded stringer.

In some cases, the stresses in the stringer did not check the computed stresses, particularly for the smaller stringer spacings, because the computed stresses only included bending stresses. Since the stringers were welded to the floor-beams, direct tension could occur in addition to the bending moments. Four types of stresses are probably added to the simple bending stresses along the tension flange: First, due to the tension in the lower flange, its length is increased, imposing compression on the ends of the beam, and thus tending to reduce the flange tension; second, due to the deflection of the beam, the longitudinal axis shortens and causes tension along that axis; and, third, due to the rotation of the bottom flange, shortening takes place which causes tension along the gage line. Finally, these effects in any one stringer have a reaction on the floor-beam which, in turn, applies a couple and a tensional stress to the other stringers.

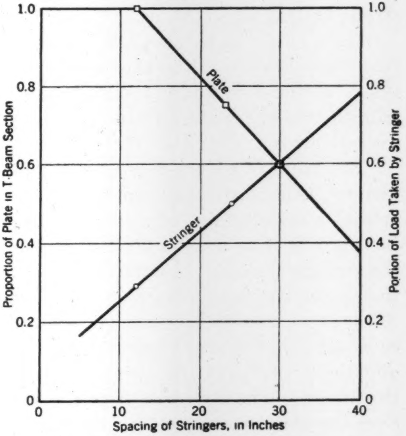

FIG. 14.—AMOUNT OF PLATE IN T-BEAM ACTION AND LOAD TAKEN BY STRINGER

The effect of these stresses is greatest on the loaded stringer as it reduces the compression and increases the tension. This stringer has a great effect on the rotation of the floor-beam which, in turn, tends to offset the secondary stresses in the adjacent stringers. In the stringers a distance away from the load, the tension is reduced in some cases to zero, and the compression is increased. Table 1(*b*) illustrates this phenomenon.

The width of plate in T-beam action was found to increase as the stringer spacing decreased, whereas the load taken by a stringer increased with the increase in spacing. Both these results are logical and Fig. 14 presents the relationships obtained. These relationships are useful for the design of battle-deck floors.

A stringer needs to be designed only for the effect of one rear wheel load since the usual axle spacing on trucks is so large that the effect of one wheel is not carried over to the other. There seems to be no need of making the exterior stringer larger than the interior stringers since it is practically impossible for the center of the wheel to come over the center of the exterior stringers. Usually, the exterior stringer will not be stressed higher than the interior stringers if it is the same size. The stringer next to the exterior will take about 5% more of the load than any of the other interior stringers, because a full wheel load can rest on it and the exterior will not help support it as much as the interior stringers. Thus, it will be overstressed about 5%, if it is the same size as the other interior stringers.

When coped into the floor-beams of a single span, the stringers had a fixation factor of about 25 per cent. When the spans were continuous, the factor was as high as 50 per cent. A substantial saving in material can be effected if this partial fixation is taken into account in design. The foregoing statements apply to web-plate connections; the fixation factors for web-angle connections were slightly smaller.

In designing battle-deck floors the smaller the stringer spacing is made, the lighter will be the resultant floor. However, the increased welding cost of the lighter floors will probably make them uneconomical unless the importance of light weight is particularly great, such as in lift spans.

The over-load tests showed that the battle-deck floor had a large reserve strength and was practically impossible to break. The tests on the full-sized floor panel would indicate that, although the measured stress was fairly high, the plate thickness could be reduced to $\frac{5}{8}$ in., or $\frac{9}{16}$ in., and still be amply strong to take an H-20 load.

Most plates in battle-deck flooring have been designed on the assumption that the plate under the load acts as a fixed-end beam. No account has been taken of the longitudinal distribution of the load. Fig. 13 shows the distribution of the plate stress. The longitudinal distribution is seen to extend over about four times the clear span of the plate, or about 84 in.

The point of contra-flexure of the plate fell close to the edge of the stringer flange. One of two assumptions may explain this: The first is that the plate acts as a simple span between the flange of stringers; and, the second is that the plate acts as a fixed beam with the point of contra-flexure at the edge of the stringer flange. In either case the result is the same, and the first assumption is the easier to use in computation. The second assumption is probably closer to what actually takes place since the plate forms a fixed beam of varying cross-section, the depth between the flanges being the depth of the plate itself, and the depth over the stringer flanges being the thickness of the plate plus the flange. The increased depth of beam at the stringers decreased the stress over the stringer far below what would be expected. The tension stress was larger than the compression stress, probably because a catenary stress of about 1 000 lb per sq in. was present.

The curve in Fig. 13(*b*) shows that the longitudinal distribution of stress varied from a peak at the center of the load, decreasing asymptotically. Neglecting the small curve at the peak, this variation may be assumed to be parabolic. Thus, the computation of the stresses in the plate becomes very simple: First, the total moment which the plate must support is computed on the assumption that the plate is a simple beam between the edges of the stringer flanges. Next, the average stress in the plate is computed over the length of four times the clear span of the plate, since the load is distributed over that distance. For the average stress this gives:

$$s_{\text{ave}} = \frac{M}{4\,S\,L} \qquad \text{(2)}$$

in which M is the moment; L, the clear span; and S is the section modulus of the plate per inch of plate. The maximum stress in the plate will be three times the average since the distribution of stress is parabolic. This semi-empirical method of determining the plate stress was used in computing the stresses in the full-sized floor and was checked by the observed stresses. The values of the stresses in the one-third sized models checked even more closely than those for the full-sized floor. This method of determining plate stresses may be expected to give quite accurate results for one-way slabs under concentrated wheel loads.

RECOMMENDED METHOD OF DESIGN

The results of the four models and the full-sized floor panel indicated that battle-deck floors may be designed by the following procedure:

(1) When the stringer spacing is determined, obtain from Fig. 14 the load taken by T-beam action of one stringer and its contributing plate width. With this information, the moment on the stringer is easily found and a trial stringer is selected. The properties of the T-beam section can be determined as soon as the plate thickness is found.

(2) When the trial stringer section has been selected for the T-beam, the clear span between the stringers is known. The trial section can be determined quite closely in the first step since great changes in the top of the T-beam change the value of the section modulus only slightly.

(3) The required plate thickness, *t*, is determined by the formula:

$$s_{\max} = \frac{3\,M}{4\,S\,L} \quad \text{.......................(3)}$$

and is found directly by changing Equation (3) to,

$$t = 3\sqrt{\frac{M}{2\,s_{\max}\,L}} \quad \text{....................(4)}$$

(4) Knowing the plate thickness, the section of the T-beam is determined, and the stresses in the stringer are computed. If the stresses are not satisfactory another section is selected.

(5) Design the stringer connections for the full load in shear.

(6) Partial fixation may be taken into account and resulting economies effected by using a fixation factor of 25% when the span is simple and 50% when it is continuous.

Wide-flanged beams, in general, will be economical since they reduce the clear span of the plate. However, the lightest wide-flanged beam may not meet the specification that the web must be at least $\frac{3}{8}$ in. in thickness. In general, lateral bracing should not be necessary for the floor when the stringers are coped in on the floor-beams.

When the plate and stringers are selected, the remainder of the floor is designed according to the usual methods. The welds between the plate and the stringers are designed for longitudinal shear. The resulting welds will also be strong enough to take care of the horizontal and catenary stresses in the plate.

SUMMARY

The results of the tests indicated that:

1.—Battle-deck flooring acts as an integral unit.

2.—Inherent welding stresses may be found in the plate but they do little harm under static load. Care in welding will minimize these stresses.

3.—A tire imposes an essentially uniform load over the area upon which it rests.

4.—The plate acts with the stringers to form a T-beam, reducing the stringer stress about 15 per cent.

5.—The load taken by a stringer and the width of plate acting with the stringer vary with the stringer spacing.

6.—The stringers distribute the load in proportion to their relative deflections; thus, the distribution is greatest when the load is in the center of the panel and decreases as the load approaches the floor-beams. The distribution factor varies with the thickness of the plate and the distance between the stringers.

7.—The plate acts as a simple beam between the edges of the stringers. The load is distributed longitudinally over a distance equal to four times the clear span. The distribution is parabolic, with the maximum stress three times the average stress.

ACKNOWLEDGMENTS

The American Institute of Steel Construction, through its Technical Research Committee, sponsored this investigation of the action of concentrated loads on battle-deck flooring, in order to obtain information for design purposes. A research fellowship supported by the Institute was established at the Fritz Engineering Laboratory of Lehigh University, at Bethlehem, Pa., and the investigation was conducted under the guidance of the Committee. Acknowledgment is due all members of this Committee for their active interest in the work and their advice and guidance. Acknowledgment is also due to the members of the Fabricating Division of the Bethlehem Steel Company for constructive criticism and valuable suggestions during the investigation, and to H. J. Bowles, Welding Supervisor, Bethlehem Steel Company, for advice and assistance in all the construction work, and to C. C. Keyser, Instructor at the Laboratory, for his assistance in the construction and testing. The full-sized floor panel was fabricated in the shops of the Bethlehem Steel Company.

DISCUSSION

H. N. HILL,[5] ASSOC. M. AM. SOC. C. E., AND R. L. MOORE,[6] ESQ. (by letter). —Having clearly recognized the essential elements of this complicated problem, the authors have proceeded logically toward an experimental study of each element. It seems to the writers, however, that certain phases of the experimental approach and the subsequent analysis of the data are open to question. The writers also feel that a word of caution should be offered against the general use of design methods empirically formulated from a limited number of tests without the benefit of a rational analysis of the problem.

The determination of the load distribution along and between stringers in a panel of battle-deck flooring, subjected to a concentrated load, is indeed a complex problem. Assuming that deflections are produced entirely by bending, the method of approach used by the authors (that of measuring slopes along the stringers and differentiating to obtain moments and shears) is theoretically sound. It is extremely sensitive, however, both to experimental inaccuracies and to slight variations in the manipulation of the slope data in obtaining the derivatives. From the nature of the level-bar readings, it was evidently not possible to obtain the slopes at the extreme ends of the stringers. As a result, the end moments and shears, which were the critical values in determining the end-fixation and load-distribution factors, were obtained from the derivatives of extrapolated curves. Fig. 7(*a*) suggests that the liberties taken in sketching in the slopes at the ends of the panels may have had considerable influence upon the accuracy of the results obtained.

That the bending moments and load-distribution factors determined in this manner are not altogether satisfactory is indicated by certain inconsistencies found between the loads carried by the different stringers and the corresponding center moments, as shown in Table 1. It would seem from the nature of the problem that the load on the stringers not carrying the wheel-load concentration would be distributed along the span according to the relative deflections of adjacent stringers. Table 1 shows, however, that for the full-sized floor the computed center moments for Stringers *B* and *D*, on either side of the loaded stringer, were greater than would have been obtained had the load computed for these stringers been concentrated at the center of the span.

Although the question of load distribution between stringers is of interest from the standpoint of analysis, the designer is usually concerned only with the maximum intensity of load and the corresponding maximum stresses that may be produced. In every case but one, given by the authors, the computed stresses in the bottom flange of the loaded stringers were less than the measured values, the difference in three cases being more than 20 per cent. As long as load-distribution factors are to be determined experimentally, it would seem that an attempt should be made to make them as consistent as possible with the maximum stresses observed.

---

[5] Research Structural Engr., Aluminum Co. of America, New Kensington, Pa.

[6] Research Structural Engr., Aluminum Research Laboratories, Aluminum Co. of America, New Kensington, Pa.

Table 1 shows that in every case the computed stresses in the top flange of the loaded stringers (plate stresses, considering T-beam action) were about twice the measured values. Although these stress differences are probably not important from the standpoint of design, the writers believe that they may be attributed very definitely to the small widths of plate computed to be effective in T-beam action. Since the end shears were determined from the second derivatives of the slope curves, multiplied by $E\,I$, any errors in the slopes, of course, would be reflected in a greatly magnified manner in the I-values. Any tendency to assume greater negative moments at the ends of the stringers than were actually present, as appears to be the case at the left end of Stringer A in Fig. 7(a), would result in high values for the second derivative of the slope curve and correspondingly low values of $E\,I$.

The authors conclude that "the width of plate acting with the stringer varies with the stringer spacing." For certain conditions of loading this statement is undoubtedly true; but it should be borne in mind that the effective width is dependent to a much greater extent on other variables. Professor S. Timoshenko[7] has shown by mathematical analysis that for certain types of loading on a wide-flanged T-beam, in which the flange thickness is small compared to the depth of the beam, the effective width of flange is a function of the span length alone. In general, however, the effective width depends not only upon the span length and type of loading, but upon the plate thickness and the elements of the stringer section as well. It may be shown from an extension of Professor Timoshenko's analysis that the theoretical effective width of plate acting with a stringer in the full-sized floor, assuming a concentrated load at the center and a span of 16.75 ft, is about 45 in. Such a width is greater than the stringer spacing, but as long as the loads on all the stringers are not of the same magnitude, there seems to be no reason for placing an arbitrary limit on effective width.

TABLE 4.—SECTION ELEMENTS FOR STRINGER C OF FULL-SIZED FLOOR

Description	WIDTH OF PLATE IN T-BEAM ACTION, IN INCHES		Percentage increase
	17.5*	45.0†	
Moment of inertia, in inches^4	427	509	19
Section modulus, in inches^3:			
Top	137	280	104
Bottom	44.7	46.8	5

* From authors' Table 2. † Computed by writers.

Table 4 gives section elements for Stringer C of the full-sized floor, assuming effective widths of plate in T-beam action of 17.5 in. and 45.0 in., as computed by the authors and writers, respectively. It is clear from the differences shown that a great increase in the effective width of the plate would have little effect on the calculated stresses in the bottom flange of stringers, but would decrease those at the top considerably.

---

[7] "Theory of Elasticity," by S. Timoshenko, McGraw-Hill, p. 156.

Using the value for computed bending moment, given by the authors in Table 1, and an effective width of 45 in., the calculated stress for the top of Stringer *C* of the full-sized panel would be 2 200 lb per sq in., as compared to a measured stress of 2 100 lb per sq in. The authors' calculated top flange stress for this stringer, using an effective width of 17.5 in., was 4 400 lb per sq in. The curve in Fig. 14, pertaining to the length of plate affected by T-beam action, can scarcely be considered accurate since it was based on values for effective width of plate that are so greatly in disagreement with the top flange stringer stresses, the only measured values which are sensitive to effective widths.

In computing the deflections shown in Table 1, the authors assumed the load on each stringer to be concentrated at the center of the span, despite the fact that the actual load distribution was presumably known from the slope measurements and the computed values of center moments given in the same table did not correspond to such a distribution. It is also apparent that shearing deformations were omitted from the values of computed deflections. The effect of shear on the deflections would not be very great, of course, producing an increase of only about 7% for the full-sized floor. The addition of this percentage, however, would produce a greater discrepancy between measured and computed values for the loaded stringer than that shown. The computed deflection of Stringer *C*, for instance, would be increased from 0.179 to 0.192 in., as compared to a measured value of 0.170 in. If an effective width of plate of 45 in. rather than 17.5 in. had been used, the computed deflection, including shear, would have been 0.163 in.

During the past seven years (1931–38) the writers have had occasion to make tests on several bridge-floor panels of the battle-deck type, and on numerous other panels in which the action was somewhat similar. All the panels tested were fabricated from high-strength aluminum alloy plates (or sheets) and structural shapes.

From measurements of the bearing areas of dual-tired wheels on large trucks, used to provide load in several field tests, the writers arrived at a laboratory loading to simulate H-20 plus 35% impact. In this loading a total load of 21 600 lb is distributed over two parallel bearing pads which are 8 in. wide and $11\frac{3}{4}$ in. in the direction of traffic. These bearing pads are of felt, 1 in. thick, backed up by steel plates 1 in. thick, and are spaced 12 in., center to center, so that the total width is 20 in. It is believed that this type of loading more nearly simulates the true wheel load than the application of a uniform pressure over a continuous bearing area.

It is questionable whether Equation (3), recommended by the authors, is adequate for the design of battle-deck floor systems of proportions different from those tested. The writers have tested floor panels composed of plates $\frac{1}{2}$ in. and $\frac{7}{16}$ in. thick on 8-in. channel stringers, spaced 11 in. apart, loaded with a truck having dual rear wheels and carrying 35 000 lb on the rear axle. With the truck so placed that the tires on each of the rear wheels straddled a stringer, the plate stresses shown in Fig. 15 were measured. It will be noticed that the transverse stresses found under the inside tires were considerably higher than those measured under the outside tires. This was true to about the same degree for both thicknesses of plate. The test was made so that the panel with the $\frac{1}{2}$-in. plate was loaded by the right rear wheel of the truck, whereas the left rear wheel was placed on the panel with the $\frac{7}{16}$-in. plate. This unequal distribution of the wheel load between the inside and outside tires may have been influenced by a number of factors, such as the deflection of the rear axle under load, the air pressures in the tires, and the extent of wear on the tires. Whatever the reason, the fact remains that this unequal distribution was obtained for a typical case of a truck in service and the existence of such a condition should be recognized.

FIG. 15.—MEASURED STRESSES IN PLATES OF BATTLE-DECK BRIDGE FLOOR

If the wheel loads in Fig. 15 are distributed between the tires in the same proportion as the ratio of the measured transverse stresses, it is found that the inside tires carried about 57% of the total, which is equivalent to a load of 10 000 lb on a bearing area of 8 in. by $11\frac{3}{4}$ in. According to Equation (3), this load would produce maximum transverse stresses of 22 800 lb per sq in. in the $\frac{1}{2}$-in. plate and 30 400 lb per sq in. in the $\frac{7}{16}$-in. plate, which values are 35% to 40% higher than those actually measured. As far as the effect of the load on the action of the plate is concerned, the writers' tests differed in two essential details from the tests described by the authors:

(1) In the writers' tests the load was distributed in such a manner that the plate was loaded on both sides of a stringer, whereas in the authors' tests the load was carried entirely between two stringers. It would seem that this difference might produce the effect of a greater degree of fixation in the plate at the stringer.

(2) The length of the bearing area (in the direction of traffic), expressed in terms of clear distance between stringers, was about three times as great in the writers' tests as in those of the authors'. This greater relative length of

bearing area would produce a distribution of longitudinal stress that would be without a sharp peak, such as that shown in Fig. 13(*a*).

The writers do not feel justified in attempting to derive an equation for maximum plate stress that would be generally applicable to this type of construction on the basis of the meager test data available. Because of the small deflections in the writers' tests (as in those of the authors') the load may be assumed to be carried entirely by bending of the plate. In the case of thin plates, however, in which the deflection might be several times the thickness of the plate, a part of the load will be carried by direct stresses, and any equation derived on the basis of bending resistance only would obviously be inadequate.

In discussing the manner in which a load applied over the center stringer is distributed laterally to the other stringers, the authors state (see "Summary," Item 6) that "the distribution factor varies with the thickness of the plate and the distance between the stringers." Nevertheless, in Fig. 14, which is recommended as a basis for design, the percentage of the total load carried by the loaded stringer is plotted against stringer spacing, with no regard to plate thickness. There are at least three other variables which affect the distribution of the load among the stringers: (1) The stiffness of the stringer (or composite plate and stringer section); (2) the width of the panel (or the number of stringers); and (3) the span length of the panel.

Since, as the authors state, the load transferred from one stringer to an adjacent stringer is a function of the difference in the deflections of the two stringers, it follows that if the stiffness of the stringers is increased the deflections will decrease and the condition of very stiff stringers and a relatively thin plate will be approached. In such a case the total applied load would be carried by the loaded stringer, regardless of the stringer spacing.

The effect of the panel width on the part of the load carried by the loaded stringer can be demonstrated by considering a panel with a large number of stringers and of such proportions that the center stringer carries 35% of the applied load, and the two stringers adjacent to the center each carry 15% of the load. The remainder of the load would then be carried by the stringers beyond the center three. If the width of the panel is decreased so that it contains only the center three stringers (which previously carried 65% of the load) they must carry the entire load.

The importance of the span length in determining the manner in which a centrally applied load is distributed among the various stringers can be demonstrated by data obtained by the writers from tests on a bridge-floor panel of the interlocking-channel type. The action of this panel was similar to that of the battle-deck type since the panel was essentially composed of a series of ribs connected by flat plates. The panel (which was 11 ft 6 in. wide) was tested on simple spans of 3-ft, 4-ft, and 5-ft lengths. Load was applied over a bearing area which had a dimension of 12 in. in the direction of the width of the panel. With a rib-spacing of only 7.25 in. and the load centered on the middle rib, it is evident that the loaded area extended almost to the two ribs adjacent to the middle. The proportion of the load carried by each rib for the different span lengths is given in Table 5. These percentages were determined from measured deflections on the basis that the load carried by each of the ribs was proportional to its deflection. Stresses measured on the bottom of each rib were substantially in agreement with such a distribution of the load. It will be noticed in Table 5 that for all spans the outside ribs were unloaded and that the center rib carried about 50% more load with the panel on a 3-ft span than when the panel was tested on a 5-ft span.

* Distributor beam at center of span.

In some of the tests made by the writers, one or more "distributor" beams were fastened to the ribs in a direction normal to that of the ribs. The function of these beams was to produce a more favorable distribution of the load among the ribs. The degree in which this was accomplished on the panel of the interlocking channel can be seen from the values in Table 5. With the distributor beam at the middle of the 5-ft span, the center rib carried only about 12% of the total load (as determined from measured deflections), whereas about 22% of the load was carried by the same rib without the distributor beam. Obviously, the effectiveness of the distributor beam will depend on its stiffness.

JONATHAN JONES,[8] M. AM. SOC. C. E. (by letter).—It would be quite futile to undertake, either by reasoning or experiment, a general solution for the case of a floor plate stiffened by ribs. Enough is known of the mathematical complexity of the problem, and of the many variables entering in, to guarantee that any such generalization, if obtainable, would be too formidable to have much practical value.

About all that is practically worth doing is to select, for the purpose in mind, an approximate arrangement of parts and sizes that promises to be successful and economical, and then, by a combination of experiment and reasoning, to develop some general rules of design that may be applied within a narrow field. This process may appear crude, but it may also be highly useful. It may not be rigorous mathematics, but it can be good engineering. This piece of research was conducted in just such a fashion, and it has produced results and recommendations of great value in its intended range, but which should not be extrapolated far therefrom.

It was the desire of the Committee of the American Institute of Steel Construction, that initiated this research, to discover the constructional advantages of the "battle-deck floor," in steel, which it believed had been obscured by the lack of a basis for design. In particular, it believed that plates of excessive thickness were being used, to the great economic disadvantage of this type of floor, simply for lack of any better method of design than a guess at a distribution, and then a continuous beam formula and the usual working stresses.

---

[8] Chf. Engr., Fabricated Steel Constr., Bethlehem Steel Co., Bethlehem, Pa.; Chairman, Committee on Technical Research. Am. Inst. of Steel Constr.

This Committee, therefore, guided the research into just those arrangements of parts in which it believed this type of construction would be most successful. Thus, it opened up the beam spacing at the expense of added weight, to minimize manufacturing costs; it discarded transverse distributors for the same reason. All this it has reported adequately elsewhere.[9] The successive models, and the final full-sized panel, were designed by the Committee, as more data became available, to come closer and closer to an economical and reasonable design.

The results have been extremely satisfactory. Within the purposely narrow range, simple rules of design have been developed by approximate analysis of the test results. Upon these rules the sponsor has compiled a booklet[9] giving recommended practice as to the arrangement of parts, beam spacing, beam sizes, plate thicknesses, etc., which give certainty of success.

Not mentioned by the authors, but important to the designer, is the choice of unit stresses by the Sponsor Institute for its recommended practice. For tension in the bottom flange of its beams, it recommends 20 000 lb per sq in., but in its tables it uses 18 000 in deference to present bridge specifications. For plate stress, it recommends 28 000 lb per sq in.

Thus, in Table 3, for the full-sized panel, it will be noted that 27 900 lb per sq in. was the conscious objective of the final design, although only 26 000 was actually measured. At first sight it may seem to be taking great liberties to propose, for regular design, a unit stress as high as 28 000 lb per sq in. As a matter of fact, it will be seen from Fig. 13 that it is truly conservative. All that this 28 000 means is a "spot" of highly stressed material backed up by a wide area of under-stressed plate; danger is impossible under such conditions. It is perhaps analogous to the, say, 40 000 lb per sq in. that exists at the edge of a hole in a tension member, but in no way is it analogous to the 16 000 or 18 000 lb per sq in., for which that member was designed.

The behavior of these floors under over-load, and their recovery on release (as described by the authors under "Test Data and Relations: Tests of Full-Sized Floor Panels"), convinced all observers that the design rules set up by A. I. S. C. will produce a floor that simply cannot be made to fail under any condition of highway service. The authors are to be congratulated upon the manner in which they fitted their technical skill into a problem which was narrowed not by, but for, them.

It is interesting to observe[10] that German engineers are also experimenting in an endeavor to reduce the weight of their highway bridge floors. As might be expected, however, they are working with designs of great complexity in order to effect a maximum saving of material; their transverse stiffeners, four-sided supports, stiffened buckle-plates, etc., represent a degree of fabrication which, in general, American designers must avoid.

[9] "The Battledeck Floor for Highway Bridges," Am. Inst. of Steel Construction, New York, N. Y., 1938.

[10] *Die Bautechnik*, June 3, 1938, p. 306 ff.

INGE LYSE,[11] M. AM. SOC. C. E., AND INGVALD E. MADSEN,[12] JUN. AM. SOC. C. E. (by letter).—An experimental solution of a complicated structural problem must of necessity be limited within the available resources. For a problem as complicated as that of the battle-deck floor system the test program had to be greatly limited in scope. Mr. Jones describes and justifies this limitation so well that it is unnecessary for the writers to elaborate on it. Mr. Jones thus answers some of the questions and criticism raised by Messrs. Hill and Moore, and since the writers subscribe in full to the discussion by Mr. Jones they will concern themselves only with other facts of the discussion by Messrs. Hill and Moore.

In discussing the bending moments and the load-distribution factors Messrs. Hill and Moore state that Table 1 gives computed center moments for Stringers *B* and *D* on either side of the loaded stringer of the full-sized floor, which are greater than would have been obtained had the loads computed for these stringers been concentrated at the center of the span. According to Table 1 Stringer *B* carried 4 850 lb; the span length is 16.75 ft; so that the center moment becomes $M_c = \frac{4\,850 \times 16.75 \times 12}{4} = 244\,000$ lb-in. against 250 000 lb-in. given in the table. It seems that this is well within experimental errors.

The width of plate in T-beam action is also questioned and reference is given to theoretical analyses indicating that for the full-sized floor panel an effective width of 45 in. could be assumed when spacing of the stringers was only 24 in. It seems to the writers that the maximum effective width could not very well exceed the stringer spacing. It should also be noted that the T-beam analysis, referred to in the discussion, is based on a single T-beam with very wide flanges, which is not the same case as the series of parallel beams in the battle-deck floor. Furthermore, the observed tension in the stringers agreed very well with the width of plate given in Table 3.

Messrs. Hill and Moore compare the results of the battle-deck steel floor with aluminum plates on channel sections. It seems that this is an extrapolation of the writers' experimental results beyond reasonable limits. The differences obtained, therefore, are what might be expected when materials and sections that differ so widely are used. It cannot be emphasized too often that experimental results of complicated structures must not be generalized to apply far outside the range covered in the experiments.

FLOOD ROUTING

BY EDWARD J. RUTTER,[1] AND QUINTIN B. GRAVES,[2] ASSOC. MEMBERS, AM. SOC. C. E., AND FRANKLIN F. SNYDER,[3] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. CECIL S. CAMP, R. D. GOODRICH, E. L. MYERS, RALPH W. POWELL, WILLIAM T. COLLINS, GEORGE E. TOWNSEND, WALDO E. SMITH, AND EDWARD J. RUTTER AND QUINTIN B. GRAVES AND FRANKLIN F. SNYDER.

SYNOPSIS

A method used for routing floods through the Tennessee River is described in this paper. First, a method for routing floods in the natural condition from Knoxville, Tenn., to the mouth of the Tennessee River was developed, and then the procedure was adapted to routing through the reservoirs of authorized and proposed projects. To analyze flood reduction, the complete river system was considered as a unit for various floods.

Routing was accomplished by dividing the river length into seven reaches and applying the storage equation to each reach. Total inflow into each reach was determined day by day from the routed outflow of the adjacent up-stream reach, published discharges of metered streams flowing into the reach, and an inflow estimated from rainfall on the unmeasured areas draining into the reach. Total flood volume at each dam site was assumed to be known. The storage in the reach for various flows was determined from topographic maps and cross-sections of the river valley in conjunction with flow profiles determined from back-water curves. The outflow was then derived from the relation of storage and discharge for the reach.

The general procedure for all reaches is described, and a detailed example for the Watts Bar-Chickamauga Reach is included. Finally, results are given for the effect of the proposed system of dams on the 1926–1927 flood and on a flood 50% larger.

INTRODUCTION

The development of the Tennessee Valley by the Tennessee Valley Authority (TVA) involves the construction of a series of reservoirs for navigation and

---

NOTE.—Published in February, 1938, *Proceedings*.

flood control, with incidental power development. The program that has been authorized by Congress includes storage reservoirs on two tributaries of the Tennessee River and a series of five high dams on the Tennessee River itself. The ultimate plan for the development of the Tennessee Valley includes the construction of seven high dams on the main river, in addition to the existing Wilson Dam at Muscle Shoals, Ala.

The determination of the reduction in flood crests that may be effected by such a system of reservoirs is a complex problem. It may be a comparatively simple matter to determine how a storage reservoir on a tributary modifies a flood flow, if stream-flow data and the storage capacity of the reservoir are known. However, the total volume of water that passes through the main river within a flood period is so great, with respect to the available storage capacity in the river reservoirs, that much study is necessary for an estimate of the reduction which these reservoirs will afford. Since river reservoirs are not level pools, consideration must be given to the water-surface profiles of each reservoir. In some of the river reservoirs the back-water effect of the dam disappears some distance from the upper end of the pools when there is a large flood discharge. The solution of the problem, therefore, requires a knowledge of the total storage in each pool which comes into use by an increase in water level—at the lower end of the pool due to the dam itself, and in the upper end due to the limitation of channel capacities. In comparing flood flows under "natural" conditions with those under conditions after the dams are built, it is necessary to determine the effect of channel or valley storage on the natural flood flows.

A complete knowledge of conditions during past floods would require copious data on channel cross-sections, topography in the valley reached by the flood, the amount of clearing within the flooded areas, and the actual profiles of the river during the high flows. It is possible to obtain much of this information, but a reliable estimate of the effect of some factors requires considerable research. (The study of floods has involved, first, as thorough an analysis of actual floods of the past as existing data permit; and, second, a determination of the effect of reservoir storage, now or soon to be available, upon floods of the past and others that may be expected in the future.) Certain reservations of storage capacity are made for flood control, but it is necessary not only to determine flood-control benefits which may be derived by the reservoir system, but also to provide data which may be necessary or useful for the proper operation of the system in flood periods.

General Information

The Tennessee River (Fig. 1) has a total length of 652 miles from its mouth, near Paducah, Ky., to the confluence of the French Broad and Holston Rivers, at Knoxville, Tenn. The valley is divided into two basins by a constriction near Chattanooga, Tenn., the upper basin being much more mountainous than the lower. The river has a number of relatively large tributaries, and many small tributary streams. The slope of the main river channel varies from rather slight slopes on the lower river to steep slopes on the upper river and at Muscle Shoals, in Alabama. Along parts of the river there are wide over-bank sections, as is the case just below Pickwick Landing Dam, in Tennessee, and in other parts there are gorge sections, as is the case just below Chattanooga. For a general description of the Tennessee River Basin, the reader is referred to the March, 1936, report to Congress of the TVA on "The Unified Development of the Tennessee River System."

Tennessee River Survey maps made under the direction of the United States Engineer Department and of silt ranges made by the TVA are important sources of information for use in determining storage in the various reaches. River-stage records and high-water marks and profiles were obtained from both published and unpublished data of the United States Weather Bureau, the United States Geological Survey, the Mississippi River Commission, and the Tennessee River Survey of the U. S. Engineer Department. Later data have been obtained and compiled directly by the TVA. Rating curves were obtained from the same sources when available; otherwise, they were constructed and extended from gage relationships taken from the river-stage records and from back-water curve computations. (Guntersville Dam, not shown in Fig. 1, is situated about 9 miles down stream from the town of Guntersville.)

Fig. 1.—Tennessee River and Tributaries, Showing Existing and Proposed Dams

General Procedure

The storage equation, "inflow minus outflow equals change in storage," has been made the basis of the routing. There are a number of solutions of this equation adaptable to flood routing, and the one used is that described by R. D. Goodrich, M. Am. Soc. C. E.[4]

In routing a flood through a reach, it is necessary to know: (1) Total inflow into reach: (*a*) Inflow at upper end of reach; and (*b*) local and tributary inflow; (2) profile of water surface at any instant; and (3) storage under the profile.

---

[4] "Rapid Calculation for Reservoir Discharge," by R. D. Goodrich, *Civil Engineering*, February, 1931, pp. 417-418.

If these three factors are known, or can be closely approximated, an outflow hydrograph will be obtained by solving the storage equation,

$$\frac{I_1 + I_2}{2}t - \frac{O_1 + O_2}{2}t = S_2 - S_1$$

in which I is the total inflow rate; O, the outflow rate; S, the volume in storage in the reach; t, the length of the period; and the subscripts, 1 and 2, refer to the beginning and the end of the period, respectively. The average inflow and outflow for a period are $\frac{I_1 + I_2}{2}$ and $\frac{O_1 + O_2}{2}$, respectively. However, if the unit of flow is cubic feet per second and the period is 24 hr, $I_1 + I_2$ and $O_1 + O_2$ give the total inflow and outflow in acre-feet, since 1 cu ft per sec for 24 hr is almost exactly 2 acre-ft. With these units the storage equation can then be written as $I_1 + I_2 - O_1 - O_2 = S_2 - S_1$, and transposing, $O_2 + S_2 = I_1 + I_2 + S_1 - O_1$. For other units and lengths of routing periods the equation must be solved accordingly.

The outflow, O_1, for the first period must be estimated, but can be closely approximated as the routing is started a day before the river begins to rise; any error made in this estimate is soon eliminated. With O_1 assumed for the beginning of the first period, I_1, I_2, S_1, and O_1 are known and determine an "outflow-plus-storage" factor, $O_2 + S_2$, for the first period. Then, with the relation between O and S known for various values of their sum, the separate values of O_2 and S_2 are determined and are equivalent to O_1 and S_1 of the following period. The four quantities, I_1, I_2, S_1, and O_1, are then known for the second period and the process is repeated.

Reaches

The first part of this study consists of routing actual floods in the natural river channel, under conditions existing at the time those floods occurred. As a preliminary, the river must be divided into "reaches" of suitable length.

In the present study of the Tennessee River, a time unit of 24 hr is used. A more flashy stream would require a shorter routing period since, in the solution of the storage equation, it is assumed that changes in rates of inflow and outflow are uniform for the period used. The length of reach should be such that the time of travel through the reach is about the same as the time unit used in routing, so that changes in the condition of inflow at the upper end of the reach at the beginning of a period will be reflected at the lower end of the reach by the end of the period, with proportional intermediate changes. The desirable length of reach in the present case is thus seen to be about one day's travel.

The ideal situation would be to have a "routing station" near the mouth of each large tributary, and as many others as necessary; but it is difficult to fix the stage-discharge relation at such points, and the ratings are seldom available. However, it is desirable to know the natural hydrograph at each dam location so that a comparison may be made between the natural peak discharge and the regulated peak discharge after the dam is built. Moreover, local and tributary inflows that have proved satisfactory in the natural condition will be available for use in routing with the dams built. The routing stations were thus fixed by the location of the dams whose potential effects on floods it was desired to study. Fortunately, all the reservoirs except Gilbertsville, in Kentucky, are close to the length corresponding to a time of travel equal to one day. Table 1 gives pertinent data for the reaches and dams considered.

RATING CURVES

Natural Condition at Dam Sites.—Most of the gaging stations on the Tennessee River and its main tributaries from Knoxville to the mouth were used in some way in this work. Where discharge measurements have been made, rating curves based on the latest data have been used. At some gaging stations where river-stage records are available but where no discharge measurements have been made, and at dam sites, rating curves have been constructed by using stage-relation curves between the gaging station or dam site in question and the nearest gaging stations which have been rated. In some cases, particularly at dam sites, it was necessary to construct or extend the rating curves by means of back-water curve computations. Only the rating curves which have been made from actual flow measurements can be taken without reservation. All rating curves constructed by other methods and all extensions of rating curves must be accepted subject to revision when better data are available.

At all routing stations except the Pickwick Landing Dam site and the Gilbertsville Dam site, the rating curves predicated a constant relationship between stage and discharge. At the Pickwick Landing Dam site a "changing-stage" rating curve was constructed to take account of slope and back-water effects. It was based on a normal curve and on two other curves—one for falling stages and one for rising stages—giving the percentage correction for each foot change of stage from the preceding day for any elevation. The normal rating curve was derived from back-water computations and other data, and the correction curves were determined by trial routings of several floods. The changing stage rating curve, then, consisted of a family of curves plotted with elevation against discharge and with the change in stage from the preceding day as the parameter, or third variable.

The method used in obtaining the Gilbertsville rating curve is similar to that developed by the U. S. Geological Survey, in the Missouri (St. Louis) District

Office, in the construction of a rating curve for the Ohio River, at Paducah. The relation between percentage submergence and a submergence factor was determined from the data available. For any percentage submergence and stage at Gilbertsville the actual discharge was obtained by applying the submergence factor to the actual stage to determine an effective stage. Then, with this effective stage, the corresponding discharge was determined from a base rating curve. For convenience, the rating curve was constructed, from the foregoing information, as a family of curves with discharge at Gilbertsville as abscissa, elevation at Paducah as ordinate, and elevation at Gilbertsville as the third variable.

Tail-Water and Head-Water Curves.—The tail-water rating curves at the dams are the same as the rating curves in the natural condition modified, in most cases, by the back-water from the nearest reservoir down stream.

The spillway discharge curves were based on the usual weir formula, $Q = C\,L\,H^{3/2}$, and were computed for unregulated conditions only; that is, all gates open. Values of the coefficient, C, were taken the same as those used by the U. S. Army Engineers.[5] When the spillway was submerged, the coefficient, C', as obtained from the results of the United States Deep Waterways experiments[6] on submerged-weir models, was substituted in the weir formula for the coefficient, C. The resulting spillway discharge curves were single-line curves, except for the Pickwick Landing and Gilbertsville Dams. At these two dams it was necessary to construct a family of curves, each member being based on a fixed tail-water elevation.

INFLOW

Inflow into each reach was divided into two parts: (1) The discharge from the reach immediately above; and (2) the local and tributary inflow, which consisted of the measured flow at U. S. Geological Survey gaging stations on the larger tributaries, together with an estimated flow from the unmeasured area. The sum of the discharge from the upper reach and the local and tributary flow is the total inflow, I, which is used in solving the storage equation. If the distance of a tributary station from the main stream is great, the flows passing the gaging station on any day were assumed to enter the main river storage one or two days later. This time lag, to the nearest day, was determined from a study of the time of travel of one particular flood.

The first step was to obtain the relation between the drainage area and the volume in the flood hydrograph at the various dam sites. This was done by plotting the flood volumes at the regular U. S. Geological Survey gaging stations against the drainage areas. The drainage area at the dam site then determined the volume of the flood at that point. The total volume to come from rainfall on the unmeasured area was determined from the difference between the volumes of the flood hydrograph at the upper and lower ends of each reach. Table 2 shows the total volume for the 1926–1927 flood at each location, the volume from the measured tributaries in each reach, and the volume from the unmeasured area. (In Table 2 the total volume in 1 000 sec-ft days is not necessarily the exact figure as taken from the total volume-drainage area relation. The total volume for the local areas is obtained from this relation, as previously stated, but the total volume shown to any point is the sum of the

* Average for the period.

discharges obtained by routing. Unless the storage stage at the end of the routing period is the same as that at the beginning and unless the outflow is the same as the inflow at the beginning and end of the routing period, the total volume of outflow cannot equal the total volume of inflow. For instance, the sum of the Watts Bar total volume of 2 297 000 and that for the area between Watts Bar and Chickamauga of 544 000 is 2 841 000 and is the volume of inflow into the Chickamauga Reach, but the volume of discharge passing Chickamauga Dam site is 2 838 000 as obtained by routing.) The distribution of the unmeasured local inflow was obtained from rainfall and a distribution graph, the latter being determined from distribution graphs of streams of about the same drainage area and shape as those in each reach herein considered. The procedure for transforming rainfall into run-off by means of a unit graph was developed by Leroy K. Sherman,[7] M. Am. Soc. C. E., and enlarged by Merrill Bernard,[8] M. Am. Soc. C. E.

In every reach the unmeasured area was relatively a small part of the total drainage area above that point, the maximum being 12.3%, so that the distribution graph could be somewhat in error without materially affecting the discharge.

---

[7] "Stream Flow from Rainfall by the Unit Graph Method," by Leroy K. Sherman, *Engineering News-Record*, Vol. 108, 1932, pp. 501–505.

[8] "An Approach to Determinate Stream Flow," by Merrill Bernard, *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 347.

The same local and tributary flows were used in the case with dams as in the natural condition, modified where necessary, of course, in accordance with the assumed operation of tributary storage dams.

The local and tributary inflow can be obtained by working backward from known daily discharges and storage on the main stream, but in every trial of this method the results were found to fluctuate. This fluctuation is due to placing all the error in the local and tributary flow, since a relatively small error in the main river discharge would be a large error in the local and tributary inflow. Then, if on one day, the computed local and tributary inflow is too low, the next day it will be correspondingly higher and the next day that much lower, etc., until negative quantities of local and tributary inflow result. However, if the fluctuating values obtained by working backward are smoothed graphically, reasonable local and tributary flows are obtained. In the example (see heading, "Example of Routing—Chickamauga Reach") given in this paper this method was not used.

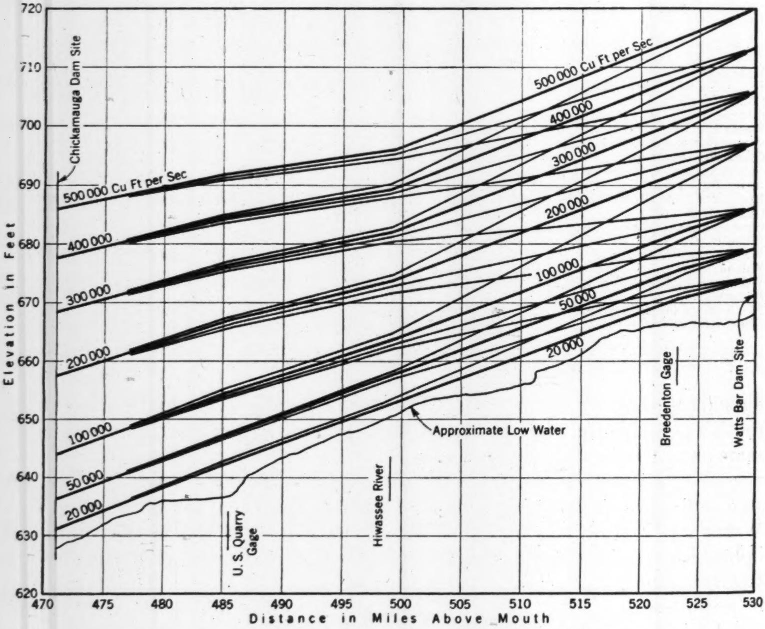

FIG. 2.—PROFILES FOR NATURAL CONDITIONS, WATTS BAR TO CHICKAMAUGA

STORAGE

Each reach was considered as a reservoir, but instead of assuming the reservoir as level, storage was computed from the volume under a sloped profile based on rating curves and back-water studies. In the natural condition, when there was a constant relation between elevation and discharge, profiles were drawn for a series of steady flows, the highest one being at least as large as the largest flood to be routed. In order to obtain a series of storage curves for use in routing that would cover the entire range of conditions, profiles of non-steady flow were drawn between the steady flow profiles. A typical set of these curves is shown in Fig. 2. The manner in which the flow was varied from the upper end of the reach to the lower end differed for each reach. In a reach where there was no large tributary, the flow was varied directly with the length of the reach; for example, with 200 000 cu ft per sec flowing at the upper end, and 300 000 cu ft per sec flowing at the lower end, the flow at the mid-point of the reach was taken to be 250 000 cu ft per sec. The elevation at the mid-point was determined by that flow, applied to a rating curve drawn from the calculated back-water curves. In reaches where a relatively large tributary entered, the flow was varied on the basis of drainage area; for example, if the drainage area from the upper end of the reach to just below the mouth of the tributary is three-fourths of the total drainage area in the reach, then the flow at that point is taken as 275 000 cu ft per sec for the same flow conditions as given previously.

To represent fully the condition after the dams are built, the storage curves for each reach must be in such a form as to satisfy any flow conditions in that reach for any fixed head-water elevation at the dam at its lower end. This is necessary because the discharge from any dam may possibly be regulated to maintain any elevation required. To provide the necessary data, three sets of profiles were drawn—one set for an unregulated condition (that is, all gates open), and the other two sets for regulated conditions of fixed elevations at the dam. The fixed elevations usually selected were the maximum flood surcharge elevation and the minimum navigation elevation. Typical curves are shown in Figs. 3 and 4, and their use is explained under the routing procedure described in the example (see heading, "Example of Routing—Chickamauga Reach").

Storage under each of the profiles was obtained by dividing the reservoirs into smaller reaches varying from 2 miles in length on the upper river to 10 miles in length on the lower river. A volume curve was obtained for each of these smaller reaches, either by planimetering a contour map or by taking cross-sections and assuming them to be average for a certain distance. Where the latter method was used, the final individual volume curves were adjusted so that the total volume from them for a horizontal pool would agree with a level-reservoir volume curve which had been obtained by planimetering the best available maps. Low-water elevation was taken as the point of zero volume for all profiles. The total storage under the profile was obtained by summing up the volumes corresponding to the elevations taken from the profiles at the mid-points of the individual reaches. When outflow-plus-storage curves were required (as in the natural condition), the discharge at the lower end of the reach, for the corresponding profile, was added to the storage. This sum was plotted as abscissa, with discharge as ordinate, and with the discharge at the

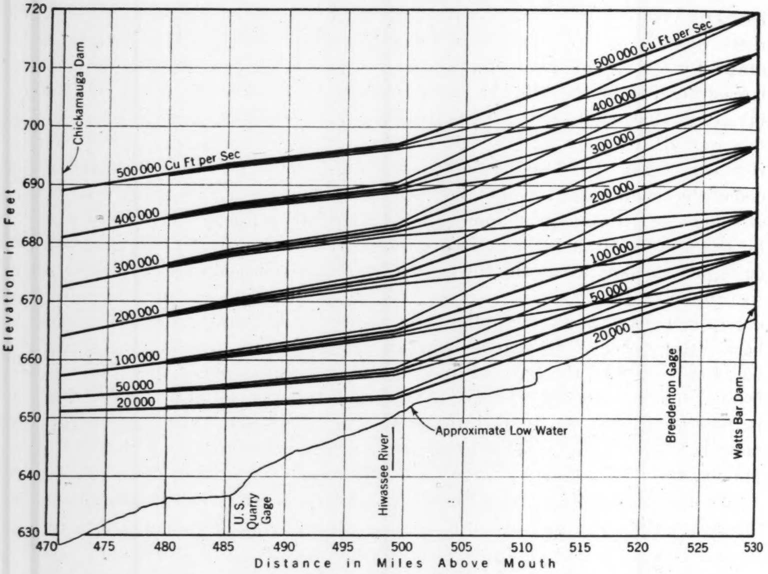

FIG. 3.—PROFILES FOR UNREGULATED CONDITION, WITH DAM, WATTS BAR TO CHICKAMAUGA

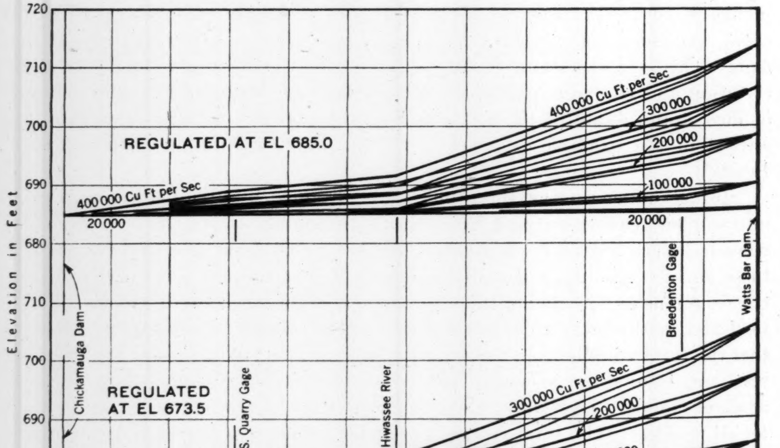

FIG. 4.—PROFILES FOR REGULATED CONDITION, WITH DAM, WATTS BAR TO CHICKAMAUGA

upper end of the reach as the parameter, thus forming a family of curves (see Fig. 5). For the conditions after the dams are built, storage alone is plotted as abscissa (Fig. 6). For each of the five upper reaches (Coulter Shoals, Watts Bar, Chickamauga, Guntersville, and Wheeler) there is one set of curves

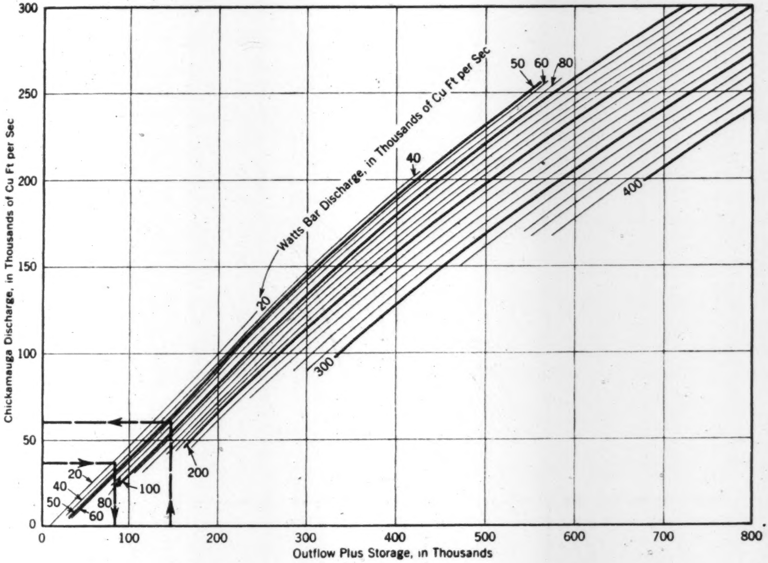

FIG. 5.—OUTFLOW-PLUS-STORAGE CURVES FOR NATURAL CONDITION, CHICKAMAUGA REACH

of outflow plus storage, for use in the natural condition, and three sets of curves of storage, for use after the dams are built.

For the two lower river reaches (Pickwick Landing and Gilbertsville) a different procedure was used for routing in the natural condition, because of the effect of slope and back-water on the stage-discharge relation. In each of these reaches three sets of outflow-plus-storage curves were constructed, based on three different rating curves for the respective dam sites, in order to allow for different discharges that can occur for any given elevation at the lower end of the reach. At Pickwick Landing, the rating curves selected were the normal curve, the 10-ft rise-in-stage curve, and the 4-ft fall-in-stage curve. The resulting sets of outflow-plus-storage curves, were plotted against the Pickwick elevation, with discharge at Wilson Dam as the third variable. In the routing procedure the true elevation, discharge, and storage are interpolated from the three sets; this process is explained under routing procedure (see heading, "Routing"). At Gilbertsville, the rating curves are based on the elevation of the Ohio River at Paducah, which is assumed to be known in all Gilbertsville routings. The rating curves used in this case were for three different percentage submergences of the Gilbertsville gage, and the resulting outflow-plus-storage curves were plotted against the Paducah elevation, with the Pickwick elevation as the third variable.

For routing after the dams are built, the storage curves for the two lower reaches were drawn in the same manner as those for the upper reaches. At all dams, when an unregulated condition is assumed, the routing procedure is exactly the same as in the natural condition, except that the outflow-plus-storage curves are based on the rating curve for unregulated head-water elevation.

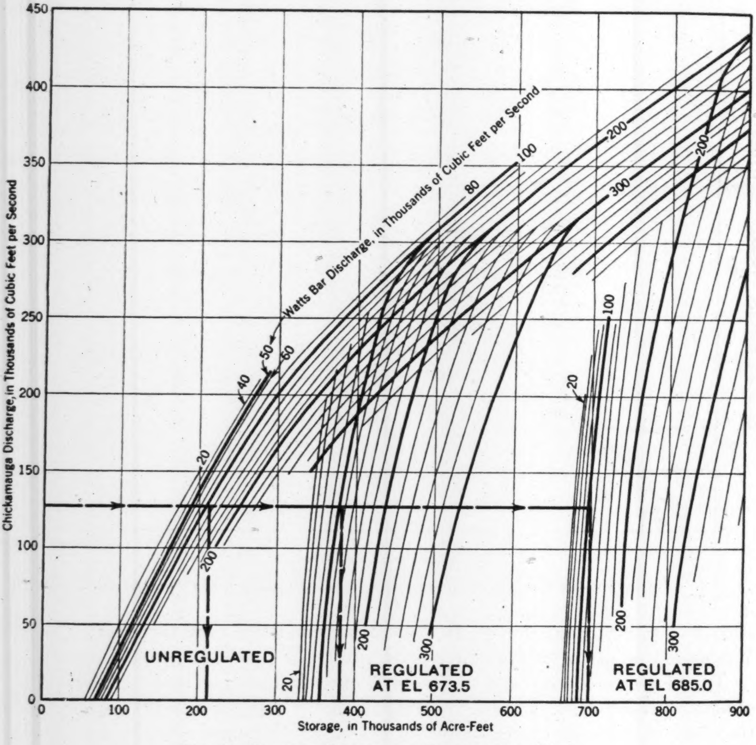

FIG. 6.—STORAGE CURVES FOR CHICKAMAUGA DAM

Other methods of obtaining storage were considered in the course of this study. Throughout the period covered by a flood hydrograph it is possible to determine the storage change on each day if the discharge at the upper and lower ends of the reach and the local and tributary inflow are known. Then, knowing the initial storage, the total storage at the end of each time period can be determined. This method has been described by Harold A. Thomas,[9]

---

[9] "The Hydraulics of Flood Movements in Rivers," by Harold A. Thomas, *Engineering Bulletin*, Carnegie Inst. of Technology, p. 65.

M. Am. Soc. C. E. The objections to its use are that the hydrograph at each end of the reach must be known fairly accurately (which was not the case in this study) and that storage curves obtained by this method are not easily adapted to the condition with the dams built. It is also necessary to have a different storage curve for each flood or an average curve based on a number of floods.

If the profiles and the storage under them are correct, it is not necessary to introduce any time element into the routing procedure, provided the length of each reach is such that the true storage within it at any time can be determined by the end elevations. The profiles show the storage at a particular instant, and the storage conditions in the entire river are considered at the same instant. It is believed that if the length of the reach is such that the time of travel is approximately equal to the time period used in the routing, the use of the two end elevations in fixing the profile of the water surface, and, consequently, the storage, will result in reasonable accuracy. The Gilbertsville Reach was the only one in which a correction was necessary to allow for an extreme length, which in this case was 184 miles. Since the time of travel in this reach is several days, a flood wave passing through the reach does not agree with the assumptions used in the shorter reaches as to surface profiles and storage.

One purpose of routing in the natural condition to check an actual hydrograph was to learn whether the routing would give an accurate indication of the time of occurrence of the peak. It was found that it did; there was no marked difference between the observed and routed time. It is an accepted fact that an increase in flow at the upper end of a reach is transmitted to the lower end more rapidly through a reservoir than along the river in its natural condition. That the routing procedure for the condition with dams automatically takes this into account will be clear from inspection of the profiles for the natural and regulated conditions for a typical reach (Figs. 2 and 4) and the corresponding outflow-plus-storage curves or storage curves (Figs. 5 and 6). For example, assume that a steady flow of 100 000 cu ft per sec throughout the reach is increased to 200 000 cu ft per sec at the upper end. The increment of storage that must be filled before an outflow of 200 000 cu ft per sec can occur at the lower end of the reach is: (1) For the natural condition, 174 000 acre-ft; (2) for the dams in place, with regulation at Elevation 673.5, 100 000 acre-ft; and (3) for regulation at Elevation 685.0, 70 000 acre-ft. The routing method thus provides for the faster passage of water through the reservoirs, and its accuracy is limited only by that of the profiles and storage.

EXAMPLE OF ROUTING—CHICKAMAUGA REACH

The Watts Bar-to-Chickamauga Reach is now discussed in detail as an example of the routing procedure.

Chickamauga Inflow.—Inflow into the upper end of this reach was made the same as the routed discharge from the Watts Bar Reach immediately above. (The Watts Bar routing is not shown in this example.)

The increase in drainage area between the upper and lower ends of the Chickamauga Reach, as shown in Table 2, is 3 400 sq miles. The run-off from 2 300 sq miles was measured on the Hiwassee River at Charleston, Tenn., leaving the run-off from 1 100 sq miles to be estimated from an average rainfall of 7.65 in. in 9 days. This average rainfall was obtained from six stations corrected to a calendar-day basis. The unmeasured drainage area is made up of many small streams running directly into the main river and, for this reason, a distribution graph was used which gave a relatively quick run-off. The percentages used were 50, 30, 12, 5, 2, and 1, which means that 50% of the run-off from a day's rain arrived in the reach on that day, 30% on the next day, etc. The total volume of run-off from the unmeasured area was obtained as follows: (1) From the total volume-drainage area relation for a 30-day period, the total flood volume at Watts Bar was 2 346 000 sec-ft days, and that at Chickamauga was 2 899 000 sec-ft days; (2) the difference (553 000 sec-ft days) of these two volumes was the total flood run-off from the area between Watts Bar and Coulter Shoals; (3) the total flood volume of the Hiwassee River, at Charleston, Tenn., was 303 000 sec-ft days, and this volume was subtracted from 553 000 to give 250 000 sec-ft days, the total flood volume from the unmeasured area; (4) the base flow of 2 030 cu ft per sec per day or 61 000 sec-ft days was subtracted from 250 000 to give 189 000 sec-ft days, the total volume from rainfall of 7.65 in. on the unmeasured area. Since there was some rainfall on the day preceding the beginning of the routing period, the quantities given for a 30-day period are somewhat greater than those shown in Table 2 for a 29-day period. The percentage of run-off was assumed to be constant for the entire storm.

The sum of the flow of the Hiwassee River, at Charleston, and the estimated flow from the unmeasured area was added, in the routing, to the inflow at the upper end of the reach to give the total inflow, I, used in the storage equation.

When the Hiwassee Dam was assumed to be in operation, the flow at that point was interpolated from the records of the Hiwassee River at Reliance, Tenn., and Murphy, N. C., and the quantity stored at Hiwassee Dam was subtracted from the Chickamauga local and tributary flow one day later than it occurred at the Hiwassee Dam site.

Chickamauga Storage.—Natural storage in the Chickamauga Reach was obtained as follows: (1) A series of back-water curves for various non-steady flows were computed, based on values of n in Kutter's formula as derived from a study of several known flood profiles and a Chickamauga rating curve determined from gage relations with the Chattanooga curve; (2) from the calculated curves, rating curves were drawn at all required points in the reach; (3) from these rating curves the elevations at the desired flows were taken and flow profiles were constructed (Fig. 2); and (4) storage under each profile was obtained by summing the 2-mile reach volumes which had been planimetered from topographic maps made in 1924 by the U. S. Corps of Engineers. To the storage was added the outflow at Chickamauga, and this sum was plotted against discharge at Chickamauga with the discharge at Watts Bar as the third variable (Fig. 5). In explanation of Step (3), it should be noted that, the non-steady flow was assumed to vary with the drainage area; for example, the drainage area between Chickamauga and the mouth of the Hiwassee River is 380 sq miles; the drainage area of the Hiwassee River is 2 660 sq miles; and the total drainage area between Watts Bar and Chickamauga is 3 400 sq miles. Then, if the flow is 300 000 cu ft per sec at Chickamauga and 100 000 cu ft per sec at Watts Bar, it is assumed to decrease uniformly from 300 000 at Chickamauga to $300\,000 - \frac{380}{3\,400}(300\,000 - 100\,000)$ at the mouth of the Hiwassee River. At that point it is further decreased by $\frac{2\,660}{3\,400}(300\,000 - 100\,000)$, and from there it is decreased uniformly to 100 000 at Watts Bar.

Three sets of profiles for the conditions after the dam is built (Figs. 3 and 4) were constructed in a similar manner. However, for the cases shown in Fig. 4 (which apply when the outflow from the dam is being regulated) the non-steady flow profiles were varied with the distance instead of the drainage area, as it was believed that with regulation the character and shape of a flood is so changed that the tributary does not necessarily contribute inflow in the same proportion as in the natural condition. Storage under the profiles was obtained from the same 2-mile reach volume curves that were used for the natural condition. In this case, however, storage was plotted against discharge at Chickamauga with discharge at Watts Bar as the third variable (Fig. 6).

Chickamauga Routing.—A sample of routing in the natural condition (the latter part of the flood has been omitted) from Watts Bar to Chickamauga is given in Table 3(*a*).

* Modified from the natural case, Table 3(*a*), due to storing in Norris Reservoir and regulation at Coulter Shoals and Watts Bar Reservoirs.

† Modified from the natural case, Table 3(*a*), due to storing in Hiwassee Reservoir.

The Watts Bar discharges or inflows at the upper end of the reach are those obtained by routing from up stream. The Chickamauga discharge, O_1, is estimated for the first day to be 37 000 cu ft per sec. From Fig. 5, using the Watts Bar and Chickamauga flows for December 21, 1926, a value of 85 000 is obtained for $O + S$, and subtracting O_1, $S_1 = 48\,000$ acre-ft. (This interchange of units of flow and storage has been explained under the heading, "General Procedure.") The total inflow, I_1, for December 22, 1926, is brought over as I_2 of December 21, and the sum of 185 000 is obtained, from which the Chickamauga O_1 of 37 000 is subtracted, giving an $O_2 + S_2$ of 148 000 for December 21, which becomes the $O_1 + S_1$ for December 22. This value of outflow plus storage, the Watts Bar discharge of 76 000 for December 22, and the $O + S$ curves determine the Chickamauga outflow, O_1, of 60 000, and the storage, S_1, of 88 000 (that is, 148 000 − 60 000) for December 22. The procedure is then repeated for as many periods as desired. Table 3(*a*) shows a peak Chickamauga discharge of 252 000 sec-ft on December 29. The elevations are obtained from the Chickamauga tail-water curve (Fig. 7). The routed hydrograph at Chickamauga is compared with the published U. S. Geological Survey discharges at Chattanooga in Fig. 8. Chickamauga is slightly less than eight miles up stream from Chattanooga.

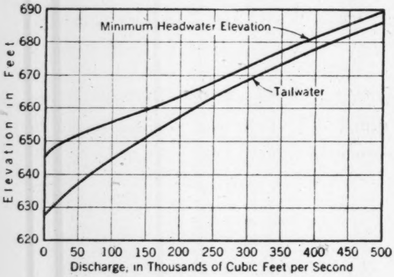

FIG. 7.—HEAD-WATER AND TAIL-WATER RATING CURVES, CHICKAMAUGA DAM

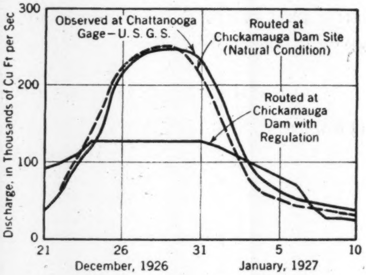

FIG. 8.—COMPARISON OF ROUTED AND OBSERVED HYDROGRAPHS

Table 3(*b*) is an example of Chickamauga routing with the dam regulating the flow. The reservoir at the dam is at Elevation 675.0 at the beginning, with an assumed drawdown to Elevation 673.5 and a flood surcharge to Elevation 685.0 (Table 1).

The constant outflow to which it is possible to regulate a particular flood without violating the assumed elevations is estimated and then checked by routing, and if a greater or less reduction is indicated, the routing is revised.

The outflows were regulated as desired and in the given example made such, from December 21 to December 23, 1926, that the reservoir elevation at the dam would be drawn down to the minimum allowable and held there as long as possible without exceeding the flow to which it was possible to reduce the main peak of the flood. The constant outflow of 127 000 cu ft per sec was made such that the reservoir elevation at the dam would not exceed Elevation 685.0 at any time.

The principal problem of routing with regulated operation of the dams is to determine the correct head-water elevation from day to day. As in all the routing, the storage on the first day must be determined from the river conditions. On succeeding days the storage is then determined from the regulated Watts Bar inflows, the local and tributary inflows, and the regulated Chickamauga outflows.

For a particular day, such as December 24, the three sets of storage curves in Fig. 6 are entered with the Watts Bar inflow of 112 000 cu ft per sec and the Chickamauga discharge of 127 000 cu ft per sec. A storage of 214 000 acre-ft is obtained from the curves for the unregulated condition, 382 000 acre-ft from the set for regulation at Elevation 673.5, and 700 000 acre-ft from the set for regulation at Elevation 685.0. The elevation corresponding to the storage for the unregulated condition is found to be 658.0 from the head-water curve of Fig. 7 for the Chickamauga flow of 127 000 cu ft per sec. The three storage values are plotted against their respective elevations (Fig. 9) and a curve is drawn through the points. Then, entering Fig. 9 with the actual storage for December 24 (395 000 acre-ft), the corresponding elevation of 674.1 is determined for that date. The process is repeated for each day.

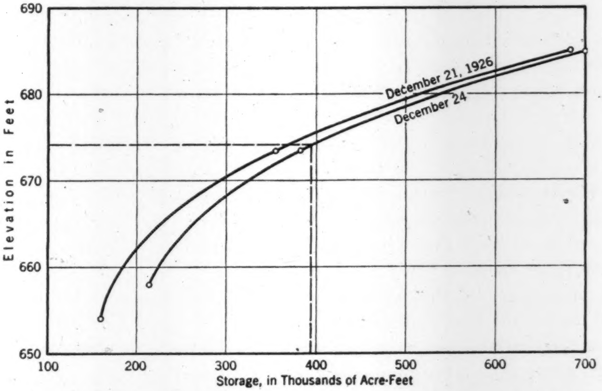

Fig. 9.—Relation Between Elevation and Storage on Typical Days, Chickamauga Reach, with Dams

The tail-water elevations are determined by applying the regulated Chickamauga discharges to the tail-water rating curve of Fig. 7.

Special Problems

In routing from Knoxville to Gilbertsville a number of special problems were encountered. The Knoxville hydrograph must be known to route through the Knoxville-Coulter Shoals Reach, and the regular procedure is then followed in routing through Watts Bar and Chickamauga.

No attempt was made to route through the Hales Bar Pool. In the natural routing the Hales Bar flows were obtained by applying gage heights to the latest rating curve and were used in routing through the Guntersville Reach. All the Guntersville storage curves were prepared on this basis.

The natural routing thus required no local inflow for the area between Chickamauga and Hales Bar. However, with the dams operating a local inflow was necessary, and it was obtained by plotting the Chickamauga and Hales Bar hydrographs on separate sheets to the same scale. The Chickamauga plotting was placed on the other and lagged in time, a distance approximately equal to the time of travel between the two points. The difference between the discharges on each day, using the date on the Hales Bar hydrograph, was taken as the local inflow on that day and was assumed to represent any storage effect of the Hales Bar Pool. These values were added to the Chickamauga regulated outflows to obtain the inflows into the upper end of the Guntersville Reach. The Guntersville and Wheeler Reaches were routed in the regular manner.

The floods were not routed through the Wilson Reservoir. For the natural condition, inflow into the upper end of the Pickwick Landing Reach was made the same as the published U. S. Geological Survey discharges at Florence, Ala. For the condition with the dams built, the Pickwick Landing inflow at the upper end was obtained by adding to the Wheeler outflow the local and tributary flow into Wilson Reservoir, allowing no time lag or reduction for storage.

The Pickwick Landing and Gilbertsville Reaches required special methods because of the types of rating curves necessary at each station; and, in addition, the length of the Gilbertsville Reach presented a difficult situation. As mentioned in the discussion of storage (see heading, "Storage"), three sets of outflow-plus-storage curves were prepared for both the Pickwick Landing and Gilbertsville natural routings, to take care of the additional variable introduced by the effect of slope or back-water.

For rising stages at Pickwick Landing the $O + S$ curves for no change of stage and for a 10-ft rise were entered with the values of $O + S$ and the Wilson flow for a particular day, and two Pickwick elevations were thus obtained. These two elevations were plotted against zero and 10-ft change of stage, respectively, and connected by a straight line. Then, by trial, a change in stage was determined from this plotting such that when added to the previous day's elevation, the new elevation was that given on the curve for the change in stage used. Falling stages were handled similarly except that the discharge plus storage curves for zero change of stage and those for a 4-ft fall were used. Having found the elevation and change of stage, the discharge for that day was known from the rating curve.

At Gilbertsville, the treatment was similar to that at Pickwick Landing, except that the additional variable taken care of by the three sets of outflow-plus-storage curves was percentage submergence. In addition, all three sets were used in the supplementary plotting to obtain the true Gilbertsville elevation.

An additional variation was made in the natural Gilbertsville routing to take care of the length of the reach. For use in entering the outflow-plus-storage curves, the Pickwick Landing elevation was adjusted. The time of travel was assumed to be about three days, and the effect of a given day's change in stage at Pickwick Landing was spread over three days.

The routing with the dams built at Pickwick Landing and Gilbertsville was slightly different from the example for Chickamauga. The difference at Pickwick Landing was in obtaining the reservoir elevation against which to plot the storage figure obtained from the storage curves for the unregulated condition. The Pickwick tail-water elevations were obtained by trial and error from the changing-stage rating curve before the head-water elevation could be obtained from the special head-water curves previously described.

For routing in Gilbertsville, the Pickwick Landing tail-water elevations were adjusted in the same manner as in the natural routing. Here, again, the tail-water elevation was obtained before the head-water elevation could be found. The Paducah elevation, corrected for the regulation of the Tennessee River, the natural rating curve, and the regulated outflow, fixed the tail-water elevation. Knowing the tail-water elevation and the discharge, the head-water elevation was fixed for use with the set of unregulated storage curves.

CONCLUSIONS

Table 4 gives the results of routing for two of the cases studied. The dams were operated in accordance with the limiting elevations given in Table 1.

TABLE 4.—PEAK DISCHARGE IN THOUSANDS OF CUBIC FEET PER SECOND AT MAIN-RIVER DAM SITES

Location	FLOOD OF 1926–1927		1926–1927 FLOOD PLUS 50 PER CENT	
	River in natural condition	Dams in place*	River in natural condition	Dams in place*

Columbus, Ky., on the Mississippi River	1 320	1 180	1 580	1 448

* Norris, Hiwassee, and all main-river dams.

Elevations at the beginning of the flood period were assumed as those in Column (5) of that table. A drawdown was used where allowed by minimum navigation limits (Column (6)). The flood surcharge elevations used are given in Column (4). It must be kept in mind that this range of operation of the dams is tentative and subject to change. The flood, 50% greater than that of 1926–1927, was built up by increasing the Knoxville hydrograph by 50% and then routing down stream with the local and tributary inflow of each reach increased by 50 per cent.

It is believed that the procedure developed gives results as accurate as can be obtained with the data available. The storage curves and profiles as compiled in this paper are not suitable for low flows or sharp-peaked floods of short duration, but with some modification they could be made applicable.

For floods as great as any that have occurred and for which fairly accurate ratings are available at the various stations, the method seems satisfactory in studying past floods or in forecasting flows for desirable operation of dams as future floods occur.

In forecasting, the beginning point at Knoxville and the local and tributary inflows must be predicted as far into the future as it is desired to forecast the main river. This is best done by consideration of rainfall and extension of tributary records as they become available.

ACKNOWLEDGMENTS

The writers wish to express their appreciation to J. H. Kimball, M. Am. Soc. C. E., Head of the Flood Control Section of the TVA, under whose direction the studies described in this paper were made; and to B. J. Buehler, Jun. Am. Soc. C. E., for reading and criticizing the manuscript; and to other members of the Flood Control Section for preparation of some of the material used in the study.

DISCUSSION

CECIL S. CAMP,[10] ASSOC. M. AM. SOC. C. E. (by letter).—The method of routing floods through reservoirs, presented in this paper, should be of value to all engineers concerned with analyzing the effect of various dams, or groups of dams, on the control of floods. The method can also be used to advantage in determining the operating schedule of a system of flood-control or navigation dams. Because of the many data on stream cross-sections and profiles required for its use, the method will probably be of more value in studies of large river systems than for single dams.

It was rather surprising to the writer that the routed natural hydrographs agreed so well with the actual stream-flow records when it is considered that there was considerable variation in the extent of the area for which local and tributary inflow was calculated from rainfall for the various floods studied. This variation was due to some stream-gaging stations not being in operation for the earlier floods studied. However, the fact that there was considerable variation in this area serves to emphasize the adaptability and usefulness of the method.

The necessity of obtaining accurate stage-discharge relations, covering the maximum possible range of these values, at the different "routing stations" cannot be emphasized too strongly. The effect of channel storage between the "routing station" and the stream-gaging stations which are used in the construction of the rating curve, must be given careful consideration. Furthermore, in those cases where the submergence factor between a down-stream station and the "routing station" is used, the rating curve must be constructed to cover the extreme values of the submergence factor that may occur when the stage at the down-stream station is affected by excessive run-off from a tributary below the "routing station," or by confluence with another stream. In studies of the 1937 flood on the Lower Tennessee River the writer found that the effect of the extremely high stages on the Ohio River, at Paducah, Ky., was such that it was impossible to check observed stages at the Gilbertsville, Ky., dam site by the use of a Gilbertsville rating curve, which had given very good results when used for several other floods in which the Paducah stages had not been so high.

R. D. GOODRICH[11] M. AM. SOC. C. E. (by letter).—The importance of flood routing is becoming greater with every added disaster and a year seldom passes without serious loss and damage in some quarter from this cause. Hence, an accurate and detailed description and record of methods, as given by Messrs. Rutter, Graves, and Snyder, is a valuable contribution to the literature on floods.

The reliability of discharge estimates and flood frequencies based on such computations as those described by the authors may be questioned by some and, therefore, when predictions based on similar studies are confirmed by later experience, one's confidence in these methods seems to be justified.

[10] Asst. Prof. of Civ. Eng., Coll. of Applied Science, Syracuse Univ., Syracuse, N. Y.

[11] Dean, Coll. of Eng., Univ. of Wyoming, Laramie, Wyo.

A case in point occurred with the floods of December, 1937, on the Sacramento River, in California. It was while engaged on a detailed study of the Sacramento Valley Flood Control Project and the probable increased protection that would be provided by the construction of the Kennet Dam (Shasta Reservoir) that the writer developed the solution of the flow-storage relation used on the Tennessee River investigation. The flood frequencies computed from the results of routing floods on the Sacramento River indicated that the location where flood damage was most probable was at Butte City, Calif., with an average probability that the capacity of the project would be equalled or exceeded about once in twenty-one years.[12] In 1915, the capacity of the project was practically equalled but with little or no damage.

A little less than twenty-five years later a flood from the Upper Sacramento River breached the levees in three places and the entire area of Butte City was inundated.[13] Great damage was also done on the Lower Feather River, in California, which the studies showed to be the next most vulnerable area in the Sacramento Valley.

Modifications and improvements in flood-routing methods are made from time to time, and the writer wishes to suggest one possibility which he utilized recently in studies on the Spokane River, in Washington. The authors used a "family of curves" for conditions involving consideration of changing stage (see heading, "Rating Curves"). To substitute a single curve the changing stage factor may sometimes be introduced into the well-known logarithmic gage-discharge relation, thus:

$$Q = A\,[(G - e) + b\,\Delta G]^n \qquad (1)$$

in which A, e, b, and n are constants for any given discharge section and ΔG is the change in stage for the period preceding any observed value of G. The discharge curve is obtained by plotting values of $[(G - e) + b\,\Delta G]$ against corresponding discharges. The constants may be found by trial or by the method of least squares. Evidently, when ΔG is very small it may be neglected and the ordinary equation of the discharge curve results.

With a single discharge curve and a single capacity curve, a very easy and rapid graphical-mechanical solution of the storage-discharge equation was suggested in a personal communication to the writer by C. O. Wisler, M. Am. Soc. C. E., which is an improvement on the method published by the writer.[4] By plotting curves for discharge and storage against corresponding elevations, two additional curves for values of $(S + 0)$ and $(S - 0)$ may also be plotted against the same corresponding elevations, as shown in Fig. 10. Elevation scales for values of $(S + 0)$ and $(S - 0)$ are then plotted below the curves with a distance apart such that an engineer's scale may be placed between them. To use this method, suppose that a value of 34 000 has been computed for $(S_2 + 0_2)$ at the end of a given period. This value will be found to occur at Elevation 2.5 in Fig. 10 and the corresponding value of $(S_1 - 0_1)$ is 15 800. Now if the grid section of Fig. 10 is enlarged to 10 in., the zero of an engineer's scale (with the same number of divisions per inch as the horizontal scale of the curves) can be placed at 2.5 on the $(S_1 - 0_1)$ elevation scale; then add the value of $I_1 + I_2$ by measuring along the $(S_2 + 0_2)$ elevation scale (say, 27 800), and the elevation at the end of the next period is seen to be 3.0, corresponding to a storage of about 43 600. The engineer's scale is then moved to the right until the zero mark comes to 3.0 on the $(S_1 - 0_1)$ scale, and the operator is ready for the value of the inflow for the next period. In this manner two computers can do very rapid routing of floods.

[12] H. R. Doc. No. 191, 73d Cong., 1st Session, p. 55, Zone 2.

[13] *Engineering News-Record,* December 16, 1937.

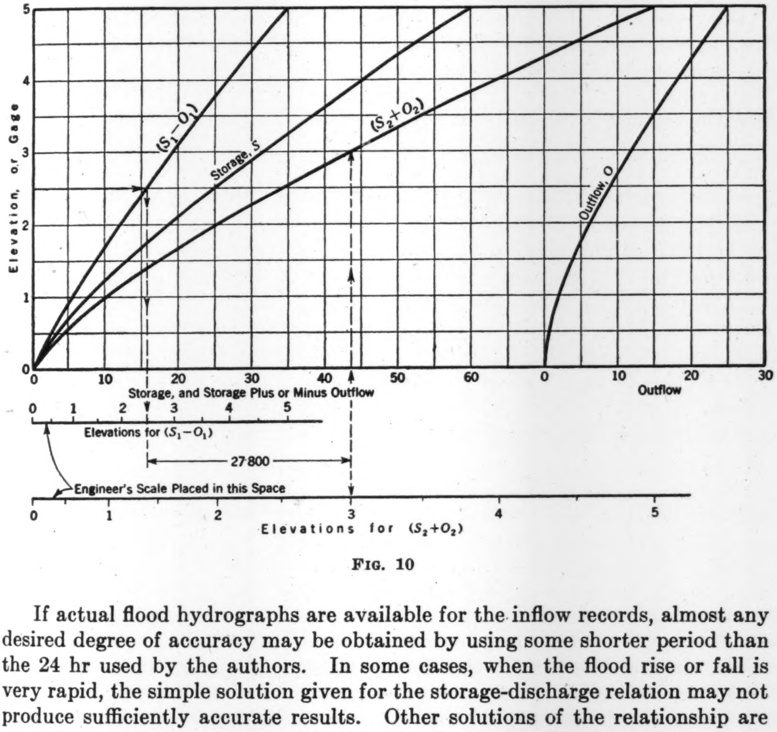

FIG. 10

If actual flood hydrographs are available for the inflow records, almost any desired degree of accuracy may be obtained by using some shorter period than the 24 hr used by the authors. In some cases, when the flood rise or fall is very rapid, the simple solution given for the storage-discharge relation may not produce sufficiently accurate results. Other solutions of the relationship are possible, as mentioned in the paper.[9] A solution for this case, which would permit the use of curves and methods similar to those used by the authors, can be made quite general by using first and second differences of inflow and outflow rates. The following equation gives one solution,

$$\left(I_1 + \frac{1}{2}\Delta I_1 + \frac{2}{3}\Delta^2 I_0\right)\frac{t}{12} + \Delta 0_0 \frac{t}{18} + \left(S_1 + \frac{1}{6} 0_1 \frac{t}{12}\right) = \left(S_2 + \frac{7}{6} 0_2 \frac{t}{12}\right) \quad \text{..(2)}$$

In Equation (2), the symbols have the same significance as in the paper, Δ and Δ^2 referring to the first and second differences and the subscript, 0, referring to a quantity determined by using the flow at the beginning of the period preceding that for which the computation is being made.

The authors should be commended for publishing this record of their exhaustive studies of the effect of reservoirs on Tennessee River floods.

E. L. MYERS,[34] M. AM. SOC. C. E. (by letter).—In a definite and concise manner, this paper describes a method of arriving at probable flood discharges and gage heights in the Tennessee Valley. This is a most constructive piece of work and should prove of great assistance to engineers making flood studies of other streams. Until recently, little information was available as to the manner of arriving at flood stages due to assumed floods. An excellent report of a flood study of the Illinois River was published in 1929 by the Division of Waterways of the State of Illinois. It was used largely by the State Reclamation Department of Texas in 1930 in a study of floods in the Trinity River.

The conditions on the Trinity River and the Illinois River, no doubt, are quite different from those on the Tennessee River; however, the general formulas used are applicable in either case. The study of the Illinois River was complicated by the existence of many levee districts which also applies to the Trinity River in a lesser degree. The effects of reservoir storage entered into the Trinity River study, but not into that of the Illinois River.

A noteworthy feature of the study of the Tennessee River as outlined in the flood-routing report is the small effect that reservoir storage has upon the magnitude of floods in the Lower Tennessee Valley. This is characteristic of most studies of flood control by reservoirs. In the case of the study of the Trinity River, it was found that prevention of floods by reservoirs was impracticable and much more expensive than protection by levees.

RALPH W. POWELL,[35] M. AM. SOC. C. E. (by letter).—Since the subject of flood routing is so important not only for flood forecasting, but also for the rational design of any system of control by reservoirs, the authors should be thanked for placing the methods they have developed at the disposal of the profession. "It is not difficult to point to cases where primary decisions on levee systems or retarding-basin systems of the first magnitude have been [in the past] based on flood-routing computations of doubtful reliability."[36] When the writer compares the elaborate studies summarized in this paper with the crude methods he used when working on the same problem of the Tennessee River, in 1927, it is striking how much progress has been made in ten years.

This is, as far as the writer knows, the first published method for routing floods through reaches affected by back-water from navigation dams, and it seems to solve the problem satisfactorily. The only questions the writer wishes to raise concern reaches not affected by back-water—what the authors call "natural conditions." In this case, cannot the method be simplified further? And cannot satisfactory routings be made without the cross-sections at frequent intervals upon which this method is based?

[34] Cons. Civ. Engr. (Myers & Noyes), Dallas, Tex.

[35] Associate Prof. of Mechanics, Ohio State Univ., Columbus, Ohio.

[36] "The Hydraulics of Flood Movements in Rivers," by Harold A. Thomas, M. Am. Soc. C. E., *Engineering Bulletin*, Carnegie Inst. of Technology, 1934 (revised 1937), p. 46.

In an attempt to answer these questions the writer secured from the authors the continuation of Table 3 through January 12, 1927, and plotted S against $O + S$ and then against $I + O + S$. As was to be expected, in the first curve, S was definitely higher on the rising stage than on the falling stage for the same value of $O + S$. In the second curve, S was greater on the falling stage than on the rising (for the same value of $I + O + S$), and the difference was larger than before. Trials were then made of $0.5\,I + O + S$; $0.4\,I + O + S$; and, $0.3\,I + O + S$, and it was found that the use of $0.4\,I$ gave the best agreement. The values are shown in Fig. 11. In this case, in determining the storage in the reach, the up-stream flow seems to have a weight of 0.4 compared to 1.0 for the down-stream flow.

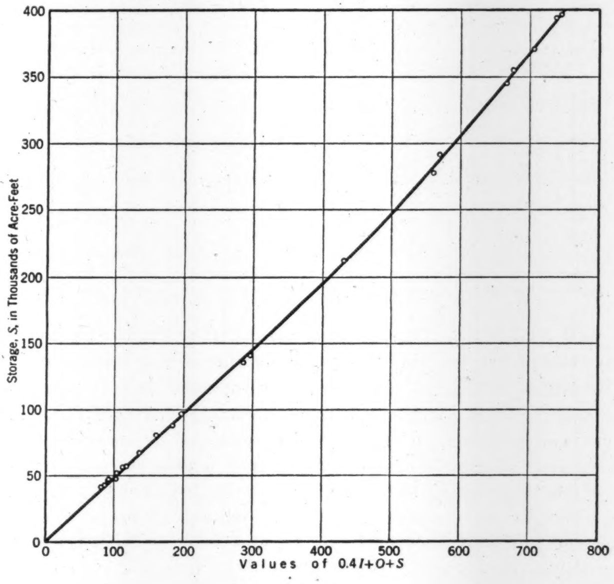

FIG. 11

Using this curve, the values in Table 5 were computed. All the values of I_1 (Columns (1), Table 5) are taken from Table 3 (and its continuation supplied by the authors); O_1 and S_1 for December 21, 1926 (Columns (3) and (4)) are also taken from Table 3. From these, are computed $I_1 + 1.4\,I_2 + S_1 - O_1 = 45 + 129 + 48 - 37 = 185$ (Column (5)) which also equals $0.4\,I_2 + O_2 + S_2$ for December 21, and $0.4\,I_1 + O_1 + S_1$ for December 22, 1926. Subtracting $0.4\,I_1$ for December 22 ($= 37$) gives $O_1 + S_1$ for December 22 ($= 148$). Entering Fig. 11 with $0.4\,I + O + S = 185$ gives S_1 (Column (4)) for December 22 ($= 89$). Subtracting this from $O_1 + S_1 = 148$ (Column (3)) gives $O_1 = 59$. The remainder of Table 5 was computed by a similar process. It should be noted that the values given are not those plotted in Fig. 11, except for the values of I; but they differ from them only slightly. The maximum difference between any value of O and that computed by the authors for the corresponding day was four units on January 2, 1927, which is less than 4% and well within the probable error of the data. In fact, on 15 of the 22 days computed, the difference was one unit or less. It seems, therefore, that if this sample is typical, the channel storage can be computed with sufficient accuracy by this method wherever accurate hydrographs of one large flood have been obtained, without the necessity of a complete flood profile and field surveys of cross-sections. All that is necessary is to make a rough estimate of the storage in the reach before the beginning of the rise (from the known length and assumed average width and average depth). Then, tabulating the known values of I and O, and starting with the assumed S_1, the other values of S can be computed by the formula, $S_2 = S_1 + I_1 + I_2 - O_1 - O_2$, and a curve like Fig. 11 plotted; or, if preferred, one may start with an assumed storage at the end of the period and work backward. In cases where the data are insufficient for making an accurate estimate of the local and unmeasured tributary inflow, this backward order would be preferred, and it is believed that it will be possible to construct a fairly accurate curve of the type shown in Fig. 11 by using the falling stage data only. For this the unmeasured inflow will form such a small part of the whole that even the roughest approximation of it will introduce little error. As has been shown by Robert E. Horton,[37] M. Am. Soc. C. E., beyond the point of inflec-

* As in Table 3, flows and storages are in units of 1 000 cu ft per sec and 1 000 acre-ft, respectively

tion of the hydrograph the flow is essentially the draw-down from channel storage, so that it should give a fairly accurate measurement of it.

---

[37] "Surface Run-Off Phenomena," *Publication 101*, Horton Hydrological Laboratory, 1935, p. 34.

Of course it should be understood that the coefficient 0.4 applies to this particular reach. For other reaches a trial would have to be made to determine whether that value or some other gave the most reasonable results. It should also be understood that no single value of the coefficient can be expected to fit the facts of all floods perfectly, or even all parts of the same flood, even on the same reach. This is only intended to be an approximate method.

As stated by the authors, Professor Thomas [9] has given a method of accomplishing this same result, but it is believed that the method herein given is simpler, and that it partly meets his objection to what he calls the first approximate method, that change of slope is "the very essence of the behavior of a flood wave," [38] and is entirely neglected in the older methods. To meet this objection more fully, the writer would recommend that if the method herein proposed is to be used for a reach in which actual gagings are available at each end, the rating curves should be drawn for a steady stage and then corrected for rising or falling stage. Perhaps a few words on this correction would not be out of order.

Professor Thomas' equation [39] can be written:

$$\frac{dy}{dx} = \frac{S\left(1 - \dfrac{Q^2}{Q_n^2}\right)}{1 - \dfrac{(u - v)^2}{g\,d}} \quad \text{. (3)}$$

in which S = slope of the water surface at the station; Q = actual flow at the station (in cubic feet per second); Q_n = flow as given by rating curve for steady flow; u = velocity of a flood wave, in feet per second; v = mean velocity of water at the station; g = acceleration of gravity, say, 32.16; and d = mean depth of stream at a station (in feet). Now if j = rate of increase of gage height, in feet per hour (negative for falling stage):

$$\frac{dy}{dx} = \frac{-j}{3\,600\,u} \quad \text{. . . . . (4)}$$

and,

$$\left(\frac{Q}{Q_n}\right)^2 = 1 + \frac{j}{3\,600\,S\,u}\left[1 - \frac{(u - v)^2}{g\,d}\right] \quad \text{. . . . . (5)}$$

As Professor Thomas states, this applies strictly only to cases in which the velocity is so low that velocity-head effects can be neglected, but this limitation would not forbid the use of Equation (5) at most gaging stations; and, ordinarily, the values of u and v will be close enough so that the last term will be unimportant. The maximum correction for changing stage occurs when $u = v$ and,

$$\frac{Q}{Q_n} = \sqrt{1 + \frac{j}{3\,600\,S\,v}} \quad \text{. . . . . (6)}$$

---

[38] "The Hydraulics of Flood Movements in Rivers," by Harold A. Thomas, *Engineering Bulletin*, Carnegie Inst. of Technology, p. 53.

[39] *Loc. cit.*, p. 25, Equation (22).

This is the same as the Jones formula used by the U. S. Geological Survey[40] except that v is the average velocity rather than the surface velocity. The use of the latter somewhat reduces the correction and, therefore, may give a better result, but actually the surface velocity depends largely on the wind, and is not a real factor in the problem. The writer is not suggesting that all flood problems require that all gage readings be converted into flow by Equation (6), but that if the data are available, the correction should be applied to the hydrographs used in obtaining the channel storage correction, as outlined herein.

It might be added that the upper part of most rating curves (if uncorrected for changing stage) are generally weighted to give falling rather than rising stage quantities, because gaging parties more often arrive at the station after the peak has passed and get a measurement on falling stage.

WILLIAM T. COLLINS,[41] JUN. AM. SOC. C. E. (by letter).—The influence of volume occupied by vegetation and of ground storage on the amount of storage for flood routing does not nullify the usefulness of volumes found from contours. This fact has been demonstrated by the authors. Heretofore, no study using that method to determine storage has been published as far as the writer knows, either because of lack of sufficiently accurate topography and data on profiles, or for lack of the perspicuity to realize that that approach could be used. To obtain the amount of storage from contours probably involves more labor than to build it up from differences of inflow and outflow hydrographs. Establishing the profiles necessary in each reach is a major hydrologic problem in itself. To those engineers who do not have the time or the data necessary to determine storage in this manner, a comparison of these storage volumes with those that might have been determined from differences of hydrographs, would be extremely interesting. Probably storage determined from hydrographs is absolutely accurate if the hydrographs are correct. Because of conditions peculiar to a flood, hydrographs are often not correct unless they are determined from rating curves based on discharge measurements made during that flood. Rating curves are usually based on measurements taken at various times; therefore, hydrographs and storage determined from them are not absolutely correct, and it would be desirable to compare storage determined in this manner with that determined from contours.

The profiles of non-steady flow are an original and logical approach to determining volumes under conditions which prevail most of the time during floods. Until now the best method of computing storage under such conditions was using storage volume as "equal to the length of the reach times the average end area."[42] This is probably all right as long as the stream remains entirely in its channel; but as soon as the flood goes over-bank, it is difficult to imagine that the end, or any sections, is typical. Gaging stations are usually located where the over-bank flow is relatively restricted, which tends to make this relation even less valid. Possibly a solution would be to find the storage from hydrographs and plot it as a function of end area.

[40] *Water Supply Paper No. 375–E.*

[41] Junior Asst. Engr., Muskingum Watershed Conservancy Dist., New Philadelphia, Ohio.

[42] "The Hydraulics of Flood Movements in Rivers," by Harold A. Thomas, M. Am. Soc. C. E., *Engineering Bulletin*, Carnegie Inst. of Technology, 1934, p. 54.

In any reach where there is a major tributary, the authors assume that distribution of discharge from the head to the foot should vary with drainage area. Consider such a reach where the stages are rising—in it inflow will exceed outflow, and discharge at the head of the reach may also (see, for example, December 22 in Table 3(*a*)). Under this circumstance the authors step discharge down at the mouth of the tributary when actually it would step up, for the tributary will always be adding some discharge. During the falling stages their assumptions closely approximate the actual discharge profile. A different treatment of local and tributary discharges might improve the method.

Tributary and local flows can be routed to the foot of the reach by adjusting time lag and distribution coefficients, or it would be possible to find the total storage and separate it according to whether it affects flow that enters at the head of the reach or that which enters along the reach. Straight-line distribution of discharge in a reach will suit conditions better, provided the stations are close enough together for the sharpness of the flood wave, if tributary and local flows are treated separately. With this plan, the discharge at the end of a reach would be the outflow as routed from the head plus local and tributary discharges. The steps in the discharge profile would come at routing stations where they are easily handled. Total storage would not be obtained under this treatment of tributary flows, but it would be approximately the storage that affects the water entering at the head. Since tributary water enters at some point other than the head, it should be treated differently from that which does enter at the head. Consider the discharge profile of a reach under two conditions: First, when head inflow is greater than outflow during a rising stage and tributaries are not adding materially to the inflow, the profile may be considered a straight line; and second, during a faster rise, when tributaries are adding, the profile will no longer be considered a straight line, but will have an increment, and, in most cases, a change of slope wherever a tributary enters. If the head inflow in the second condition is the same as before, if the outflow of water that entered at the head is less than in the first case, and if the tributaries have added enough so that the total outflow is equal to that in the first case, the authors' method would give the same storage in the two cases. The storage in the second case may be less, equal to, or more than, in the first case, depending on the position of the tributaries and whether or not they have risen or fallen since the time that their discharge influenced the present outflow. These conditions, which are redundant with the present treatment, would not be so if tributary and local flows were routed separately.

It should not be taken as general, that "the distribution graph could be somewhat in error without materially affecting the discharge computed for the main stream." On the Muskingum River, the drainage area at Zanesville, Ohio, is 6 839 sq miles, and the local and tributary area from Dresden, the station next above, is 857 sq miles, 12% of the whole. The crest at Zanesville is in some cases caused by the tributary which is flashy, and at those times occurs when the tributary adds its sharp crest to the relatively flat hydrograph of the main stream. The tributary may add as much as 35% to this crest, so that in this particular case it is necessary to know the tributary accurately.

The Muskingum Watershed Conservancy District uses curves similar in purpose to those of Fig. 9. It is realized that the outflow influences the regulated profiles of Fig. 4. However, it is easily seen that the flow at the head of the reach has more weight in determining the amount of storage. The curves made up by the District are for various uniform flows throughout the reach, and since the effect of variation of outflow from inflow is ignored they are drawn in permanent form. There is one other difference, the District being primarily a flood-control agency its interest is in the storage available for flood reduction, and its curves show what is called net reservoir storage, which is the difference between actual storage for the range of reservoir water-surface elevation at each of the chosen flows, and the storage for the same flows in the natural state without the dam.

The accuracy of the authors' method is stated to be satisfactory, but no comparison with other methods or percentage of this accuracy is given. It might have been advisable to route to the stations at which hydrographs of the floods studied were available, as well as to the stations at the dams where the main interest is. This would allow comparison of computed with actual hydrographs for the same stations.

GEORGE E. TOWNSEND,[43] JUN. AM. SOC. C. E. (by letter).—In this flood routing paper, the authors state that the time period is 24 hr, but that in routing on flashy streams a shorter time period is required. When any inflow hydrograph shows a sharp change from rising to falling stage, or when it shows marked differences from day to day, a shorter period should be used in order to give more accurate results. The necessity of a routing having shorter time periods is definitely shown when a greater peak outflow than peak inflow is found when using a longer time period. The peak outflow cannot be greater than the peak inflow because, on the rising side of the hydrographs, the stages are rising and a part of the inflow goes into storage. As long as some of the inflow goes into storage, the outflow will always be less than the inflow, until the peak of the outflow is reached. The condition is unusual and can be eliminated by the use of the shorter time period.

Fig. 12 shows a comparison between routings using the 24-hr and the 6-hr time period. The reservoir projects were operated at normal depressed winter elevations for each of the main Tennessee River dams, and all the flow was stored at the tributary reservoir projects above Knoxville, Tenn. The hydrographs apply to the Chickamauga Reach. The use of the 24-hr period gives an outflow about 11 000 cu ft per sec greater than the inflow. The application of the 6-hr time period results in an outflow peak discharge slightly less than the inflow and occurring 12 to 18 hr before the peak, as determined in the 24-hr routing. In addition, the outflow hydrograph is crossed by the inflow hydrograph nearly at the highest point of the outflow hydrograph, a criterion which usually may be applied as one check upon the results. The differences in the computed outflow hydrographs using the two different time periods may be accounted for by the impossibility of determining any flow profile to fit all flow conditions, and to the difficulty of determining an accurate local inflow. Upon the flow profiles, of course, depend the storage curves which are used in the routing. The method used in obtaining the local inflow gives good average results, but its determination depends on taking into account the water losses, the season of the year, and the condition of the ground during the particular flood. The results, therefore, are not accurate.

---

[43] Junior Hydr. Engr., Tennessee Valley Authority, Knoxville, Tenn.

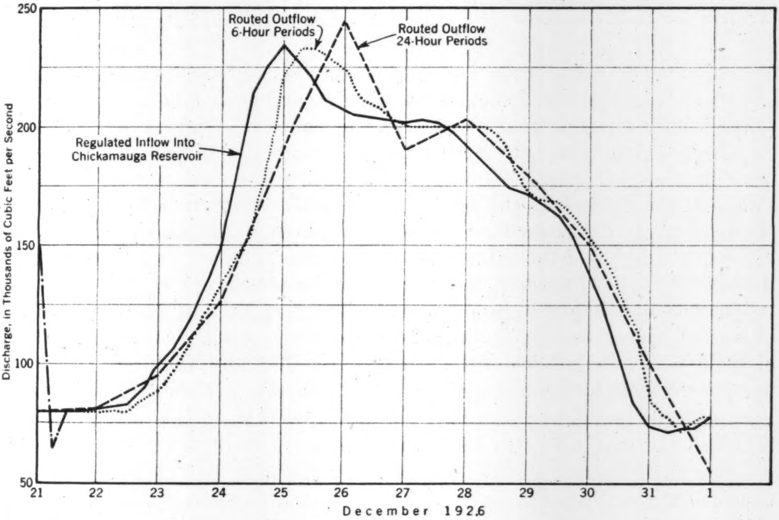

FIG. 12.—COMPARISON OF 1926 FLOOD HYDROGRAPHS AT CHICKAMAUGA DAM SITE USING 24-HOUR AND 6-HOUR PERIODS IN ROUTING

The method of using the shorter time period when it is required does not entail much extra work. It can be accomplished with the same sets of storage curves used in the 24-hr routing. Since available discharge or stage records often indicate the average day's flow or the rate of flow at a certain hour, it is advisable to convert these records into discharge curves or hydrographs. Then, from the curves, or hydrographs, the probable rate at any hour or the total for any period may be taken. The flow into the upper end of the reservoir and the local and tributary flow into the reservoir are adjusted in that manner. The sum of these two flows for each period is the flow at the beginning of each period, termed I_1, in the paper. Then all values of I_1 are divided by 4 if the time period desired is 6 hr. Next, the outflow at the beginning of the period (O_1) is found in the usual manner, but it is converted to $\frac{O_1}{4}$ so as to find the storage at the beginning of the next period (S_1) and to find $O_2 + S_2$. Several other methods may be developed, but this one may be applied to both natural conditions and to those with regulated conditions. If the storage curves for the natural conditions, however, are in the form of "outflow-plus-storage," these curves must be put in the form of "storage" alone before this method may be applied.

Also, in Fig. 12, is shown the use of two different starting flows and their result on the computed outflow hydrograph. The lower starting flow is one in which the outflow is assumed equal to the inflow to start the routing which is usually just about the actual condition at the start. The other starting point, the higher flow, can be seen to dip sharply immediately in the first 6-hr period used; but the satisfactory part about it is the rapidity with which it gets back to the original outflow hydrograph with its 6-hr period. This demonstrates that practically any outflow may be assumed to start a routing and that, regardless of which one is used, the critical peak point is not affected. Furthermore, it shows that small errors in curve reading are compensated for within several periods in the routing procedure.

A simple check on the arithmetic of a routing computation is convenient. First, all the inflows at the beginning of each period are added. Then a "correction" is determined which, when applied to the summation of the inflows, should equal the summation of all the outflows. To find this "correction" the inflow, outflow, and storage are considered for the first and the last periods of the routing computation. The first and last periods are used because the actual routing computation involves the period between the middle of the first and the middle of the last periods. Actually, the first half of the first period and the second half of the last period do not enter into the total volume of the routed hydrograph. The difference between inflow and outflow, in which the unit is in day-second-feet, therefore, is divided by 2. This is done for both the first and the last period. The difference between storages, in which the unit is acre-feet on the first and the last period, is divided by 2 to convert it to day-second-feet. The sign applied to the flows is negative when the inflow exceeds the outflow. If the storage in the last period is larger than in the first period, its sign is negative. Finally, the algebraic sum of these three corrections is applied to the summation of all inflows at the beginning of each period, and this should equal the summation of all the outflows.

Using Table 3(*a*) the correction for December 21 is 37 − 45 = − 8 day-sec-ft; for December 31, it is 211 − 170 = + 41 day-sec-ft; and for the storage correction the difference between December 21 and 31 is 48 − 291 = − 243 acre-ft. Then, $\frac{-8+41-243}{2} = -105$ day-sec-ft; and,

$$\begin{aligned} \Sigma I_1 &= 2\,045 \text{ day-sec-ft} \\ &\underline{-\ 105} \text{ day-sec-ft} \\ \Sigma O_1 &= 1\,940 \text{ day-sec-ft} \end{aligned}$$

which checks.

Possibly, some improvement may be made in the manner of determining a set of storage curves for the Tennessee River. Another method might take care of bank storage and water losses, where the authors' method does not, because storages were determined through the use of topographic maps. The manner in which the flow is varied from the upper end of the reach to the lower end might be changed so that better routing computations would result. Good results are obtained in reaches where a relatively large tributary enters near the middle of the reach, and the flow is varied on the basis of the drainage area. In reaches where no large tributary enters and the flow is varied directly with the length of the reach, results are only fair. Floods in which there is a sharp peak do not work out as well in reaches where the storage curves were made up by varying the flow with the length of the reach. Floods with a peak of long duration seem to yield better results; and, better results might be obtained if the flow were varied by a curve instead of a straight line between the upper and lower end of a reach in which no large tributary contributes its flow.

Waldo E. Smith,[44] **Assoc. M. Am. Soc. C. E.** (by letter).—The authors are to be commended for their splendid contribution to hydraulic literature pertaining to the routing of floods. The writer is pleased to note that their method abandons completely the old conceptions of prism and wedge storage and likewise circumvents the seemingly insurmountable step from theoretical and approximate formulas for uniform slopes and channels to their application to actual channels of varying section and slope. Furthermore, after the preliminary work is complete and the basic curves are computed and plotted, the method is expeditious and is satisfactory for use for analytical purposes especially, and for limited use in forecasting and in operation for the flood control of a reservoir system applied to the natural channel and channel reservoir reaches.

Flood-routing problems, quite naturally, resolve themselves into two quite distinct although overlapping parts, the first of which, in turn, is further divided into two aspects, as follows:

(1) The routing of floods in natural channel and channel reservoir reaches:
    (*a*) For analytical purposes, such as the critical survey of the operation and routing undertaken during the progress of a flood; and,
    (*b*) For forecasting and flood-control operation of reservoirs.
(2) The routing of floods through comparatively deep, broad, valley reservoirs in which the back-water transition curve is a negligible item in the volume of flood storage available. (The latter may likewise be subdivided but that subdivision is not pertinent to the subject as developed by the authors.)

The work of the authors is especially applicable to Problem 1(*a*). It can be used in forecasting Problem 1(*b*) also, but only to the extent that the upper end of the uppermost reach may be forecast.

The authors mention that the time of travel through the reach should usually be about the interval used in the analysis and that, in most cases, this appeared to be about 24 hr. The Muskingum Watershed Conservancy District has a method under study and in partial use that facilitates forecasting to successively later times as progress is made down stream. Assuming the period of forecasting to be for 24 hr, the technique developed by the District bases the forecasting for the lower station on the inflow into the reach at the present time, the anticipated storage in the reach 12 hr hence, and the local inflow 24 hr hence by the distribution graph method. Upon the completion of a storm, knowing the run-off factor, the forecaster can complete his work for the remainder of the flood period. By the District method it has been found, if the time of travel is 24 hr, that 12, 6, or 4-hr intervals can be used in routing as satisfactorily as 24 hr. The time interval use should never be greater than the so-called time of travel through the reach but it may be less. The development of outflow-plus-storage curves appears to have the effect of limiting the use of these curves to 24-hr periods. In the District work on analytical studies, the stage at the lower station has been based on estimating the outflow at the same instant of time that the inflow is known, similar to the work outlined by the authors.

---

[44] Hydr. Engr., Muskingum Watershed Conservancy Dist., New Philadelphia, Ohio.

The writer acknowledges that there is a substantial difference between the problems on the Tennessee Valley and those of the Conservancy District. In the former the upper end of the uppermost forecast reach drains about 9 000 sq miles and the routing is carried through a system of reservoirs that are essentially channel reservoirs. The total drainage area involved in the Conservancy District, on the other hand, is only 8 000 sq miles and the reservoirs are largely head-water reservoirs with storage capacities relatively large in comparison to the water-shed above; and routing and forecasting on the main streams are almost entirely in natural channels. The forecast method used by the District is found not to be uniformly applicable to all reaches, and, in some reaches, in which a large tributary enters, it has not yielded a satisfactory solution. It has been necessary to use a number of variations in the general procedure.

The authors were fortunate indeed to secure contour maps of the channel and valley floor which gave them the opportunity to determine storage in 2-mile reaches by means of contours and the profile of the stream. They were fortunate even to have cross-sections at sufficiently representative and frequent intervals. Such maps and cross-sections are not usually available and one must rely on the hydrographs to find the valley storage at any particular time for a past flood, for the development of the storage curves. This has the disadvantage of involving the local inflow and its distribution with regard to time as well as valley storage and the difference between the two hydrographs at any particular time is thus a function of two independent variables which can only be determined by trial and error. The volume of local inflow is determined by means of the hydrographs as outlined by the authors; but one must realize that this throws the entire cumulative error in rating curves into the local inflow which is usually the smallest part. The procedure on the work of the Muskingum Watershed Conservancy District has been to assume an apparently reasonable distribution graph and determine the valley storage in a reach for a given flood on this basis. A storage curve, usually with a hysteresis loop, is found and smoothed up, and the distribution coefficients are modified accordingly. Analyzing a second flood of similar magnitude, using the same distribution graph, the new storage relationship is determined, which usually differs from the first. The distribution graph is then adjusted to bring the two curves as closely together as possible and the resulting channel storage relationship is used. Local inflow in all cases has been applied to the lower end of the reach, however, instead of at the upper end as has been done by the authors. This has the tendency to change the characteristics of the distribution graph considerably, giving a relatively small percentage of run-off for the first day (or other time interval) and a much larger percentage on the second day. The effect is substantially the same, but the technique used by the District makes it convenient to find the discharge at the lower end of the reach and then add the value for the local inflow to establish the forecast gage height.

One of the difficulties of the old prism and wedge storage idea was that it failed to take into account the fact that the flood crest, or the trough between crests, is sometimes between the limits of the reach. Either condition alters prism and wedge valley storage substantially. The authors seem to offer no means of overcoming this difficulty inasmuch as the method assumes a constant rate of change of inflow, outflow, and, thus, the storage rate for each 24-hr routing period. The same problem has been a stumbling block in some cases with the forecast method used by the District outlined briefly; but by using a shorter interval than the time of travel in the reach it has been possible in some instances to compensate for it satisfactorily.

The back-water transition curves in Figs. 3 and 4 scarcely appear to be typical even of channel reservoirs. If the straight lines indicated for the profile are chords of the actual curve and were used as shown, it appears that a large thin volume of storage is included between the Chickamauga Dam and the Hiwassee River that is not actually available because of the tendency for the profile in the reservoir to be concave upward and to be nearly horizontal at the dam.

There is one question that the writer raises in connection with the speeding up of the flow through the channel reservoir. The authors have indicated that they believe that the fact that it takes less storage to increase the flow a given amount down stream compensates satisfactorily for this. The writer is not sure that this is complete compensation if the time of travel is decreased substantially. The writer would also like to know why, in the first instance, O_1 must be estimated or assumed if there is a gaging station at the lower end of the reach?

EDWARD J. RUTTER,[45] AND QUINTIN B. GRAVES,[46] ASSOC. MEMBERS, AM. SOC. C. E., AND FRANKLIN F. SNYDER,[47] JUN. AM. SOC. C. E. (by letter).—The writers appreciate the interest shown by the discussions of this paper. Several interesting suggestions have been given which add to the treatment of the subject.

Mr. Camp raises the question as to the accuracy of discharges at a "routing station" which is affected by confluence with another stream. This factor is an important feature in any stage-discharge relation, and the more accurately the relation is known the more accurate will be the discharge and elevation obtained by the routing method described in the paper. It should be noted, in studies of the 1937 flood on the Lower Tennessee River, mentioned by Mr. Camp, that the reason observed stages at the Gilbertsville, Ky., dam site were not checked is that the rating curve had to be extended into a region where no measurements of flow were available and an extremely high submergence obtained.

Mr. Goodrich offers an improvement on his method of routing with a single discharge curve and single capacity curve. It does not seem possible, however, that the graphical-mechanical solution is more rapid than his earlier method, which was readily adapted to the writers' problem of using sloped storage instead of level storage.

Mr. Myers mentions several flood studies which have been made and compares them in a general way with those on the Tennessee River. As the flood wave travels down stream the effect of up-stream tributary reservoirs tends to become less, the percentage of uncontrolled local area becomes larger, and the natural hydrograph becomes broader. All these factors combined tend to reduce the reservoir storage effect, provided there is insufficient main-river reservoir storage to counterbalance that tendency.

Mr. Powell has demonstrated a procedure for routing floods in the "natural condition" through a reach of a river for which the storage quantities were based on a study of past floods and not necessarily on storage obtained from topographic maps or cross-sections. He has, effectively, eliminated the storage loop that is obtained when storage is plotted against outflow alone. This requires accurate stream-flow records to determine the values of storage in the reach for various values of inflow and outflow. Difficulty might be experienced if it were necessary to extend these data to take care of floods considerably larger than any experienced to date, although the curve of Fig. 11 could be extended reasonable amounts.

It is desirable to use the same routing method in the "natural condition" as in the condition with the dam in place. No accurate check can be made on any procedure for routing through a reservoir created by a dam until after the dam is built. The writers believe that by treating the two cases as nearly as possible in the same manner, and by making as accurate a check as possible on the "natural condition" routing, the results obtained for the case with the dam in place will be more reliable.

The writers have applied Mr. Powell's procedure to several different conditions and have found that it will give satisfactory results. It should be noted, in his discussion, that the inflows used in Fig. 11 are also used in the routing shown in Table 5, and that all results depend on the routing method of the writers and are not taken from any really natural flows. This does not constitute an adequate check on the method for use with other floods; hence, the writers used Fig. 11 on flows for the Chickamauga reach for February and March, 1917, and for March and April, 1936, the results (Table 6) of which indicate very clearly that Mr. Powell's procedure will work satisfactorily. His procedure was then tried on three other reaches and the factor, $0.4\ I + O + S$, was found to vary according to the conditions of the reach. Having found the curve for another reach (similar to Fig. 11), other floods were routed using this curve. All results indicate a workable procedure.

* January 1.

Another condition that affects the value of the coefficient 0.4 is the relation between the up-stream flood and the local flood. A comparison was made between Mr. Powell's method and the writers' method for two cases—(1) assuming no local flood; and (2) assuming no up-stream flood. As expected, the peak storage value was smaller in the first case and larger in the second as compared to that from the curves in the paper. Table 7 shows the comparison for the two cases.

For the "natural condition," Mr. Powell's procedure is simpler than the writers' method, as far as curve reading is concerned, but required calculations are increased; hence, the type of procedure to use depends upon personal preference, or upon original information available.

Values of $0.4\,I + O + S$ were computed for the Chickamauga reach for the case with the dam in place, with regulation to several different elevations and with no regulation. These were plotted against storage, and intermediate curves for actual use were interpolated. With this set of curves, direct routings are possible without resorting to a trial-and-error procedure as in the writers' method. However, additional arithmetical work is involved, as in the "natural condition." There is one other point to consider, namely, the $(0.4\,I + O + S)$-curves for use with the dam in place must be taken from routing curves similar to those developed by the writers when making a study of a dam which is to be constructed.

Mr. Collins' criticism of the assumed profile which gives a decrease in flow at the mouth of a large tributary at the beginning of a rise (December 22) is a valid one. However, the actual value of storage cannot be greatly in error since the large tributary is near the middle of the reach. The assumed flows at the upper end of the reach, just above the tributary, just below the tributary, and at the lower end, are 76 000, 74 000, 62 000, and 60 000 cu ft per sec, respectively. The actual flows at the same points are approximately 76 000, 62 000, 74 000, and 60 000 cu ft per sec, respectively.

Mr. Collins is correct in his statement that, for some reaches, it may be better to treat tributary flows separately and add them to the routed main stream outflow at the lower end of the reach. This is particularly true of a tributary that enters the reach close to the lower end, and, consequently, has a relatively small effect on the storage values. However, by the same reasoning, the flow from a tributary which enters near the upper end of a reach should be routed with the main stream flow. Considerable study is necessary to determine if, and when, separate routing of tributary flows would be required. Each reach must be treated as a separate problem, and the procedure that gives the best results should be used. As stated in the paper (see heading, "Reaches"), the ideal procedure is to have routing stations at the mouth of all large tributaries.

Mr. Townsend presents a comparison of routing with 24-hr and 6-hr time periods, with the same inflow. In the case shown, the inflow has a relatively sharp peak, due to the method of operation used, and hence the reach assumes the characteristics of one in which a shorter time period than 24 hr gives more reasonable results. The method of checking the arithmetic described by Mr. Townsend is convenient and rapid. However, it does not check the reading of curves; these must be read again for a complete check. Mr. Townsend also notes several points in which improvements might be made in the procedure but gives no suggestions as to the method of making these improvements. Possibly more study would reveal better methods for the determination of the non-steady flow profiles in some reaches.

Mr. Smith is partly correct in his statement that, if the time of travel in a reach is 24 hr, 12-hr, 6-hr, or 4-hr intervals can be used as satisfactorily as 24-hr intervals, although this would not be the case for a reach with little local or tributary inflow. Since the interval should be determined by the stream characteristics, the use of shorter intervals in routing adds to the work without materially increasing the accuracy. The same base data used in plotting the outflow-plus-storage curves for 24-hr periods can be used to plot similar curves for any time interval desired. For example, if a 6-hr routing period is required, the outflow O would be plotted against $O + 4\ S$, instead of $O + S$.

The back-water profiles shown in Figs. 3 and 4 have the same general appearance as those in Fig. 2 for the natural condition. At the time these curves were computed, every reasonable attempt was made to eliminate any sharp changes of slope, and the lines shown represent, as nearly as possible, the profiles that might occur. Probably, after the reservoir has been constructed and operated through several floods, a revision could be made in the shape of the profiles of water surface.

Mr. Smith questions the speeding up of flow through the reservoir. The writers have based the storage on the back-water profiles. If the profiles are correct for the flow conditions indicated, the discharge at the dam cannot increase faster than the corresponding inflows, profiles, and storage allow. The change in time of travel is shown in the shape of the profile, and as a result, the value of storage is different.

The value of O_1, in the first instance, need not be assumed nor estimated for an actual flood if there is a gaging station at the routing station. For hypothetical floods and at all routing stations where there has been no gaging station the initial value of O_1 must be estimated.

PIN-CONNECTED PLATE LINKS

BY BRUCE G. JOHNSTON,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. HAROLD D. HUSSEY, AND BRUCE G. JOHNSTON.

SYNOPSIS

Results of 106 tests of differently proportioned steel plates are presented in this paper. The specimens were loaded in tension by means of 3-in. steel pins which passed through holes in either end of the plate. The effects of plate thickness, side and bottom edge distances, and pin clearance were studied in relation both to the general yield and the ultimate strength of the links. The "dishing" phenomenon, which greatly reduces the ultimate strength of thin plates unsupported laterally, was given particular attention. Empirical formulas are given for predicting the general yield and ultimate strength of the plates, together with formulas for producing a pin-plate connection of balanced design.

INTRODUCTION

The design of steel eye-bars has developed an accepted practice in regard to the relative proportions and distribution of material in the eye-bar head. The present investigation is concerned with pin-connected plates which do not have reduced width in the body as in the case of the forged eye-bar, but which are made simply by boring pinholes near the ends of structural steel plates. Examples of this type of connection are found in steel sheave blocks, derrick tackle, anchorage bars for cables, and various types of erection equipment. Although the plates tested differ from forged eye-bars, their action around the pinhole during the progress of failure is similar to that in the eye-bar head.

The problem of designing such pin-connected plate links was encountered on a large scale in arranging the hangers for raising the suspended span of the Quebec Bridge.[2] Tests were made both on model links and on full-sized hangers with 12-in. pins, and the results show a good correlation with those of the present tests. The general relation between plate thickness and "dishing" of thin plates was noted in the Quebec tests.

The bibliography on the subject of stresses in plates around pinholes is extensive, but most of it is concerned primarily with the study of stress dis-

---

NOTE.—Published in March, 1938, *Proceedings*.

tribution in the elastic range. References to various photo-elastic, mathematical, and experimental studies of the stresses in eye-bar heads may be found in the work of Professor S. Timoshenko.[3] Mathematical stress analyses require an assumed distribution of bearing pressure between pin and pinhole as a starting point. The actual bearing stress distribution depends on pin clearance and varies somewhat during the application of load. The maximum stresses are localized and, for ductile materials, the initial yielding is restrained from rapid progress by surrounding low-stressed areas and, in the early stages, has no appreciable effect on the elastic behavior of the link as a whole. Furthermore, these localized stresses have practically no effect on the ultimate strength of the link under static load. Hence, the use of a ductile material such as structural steel is very advantageous.

Local yielding in the plate at the contact point, except in the case of tight-fitting pins, will occur even at working loads. The general, or over-all yield at the end of the plate, occurs at a much later stage than initial local yielding. The term, "general yield point," will be used herein to designate the load or average bearing stress at which the slope of the curve of load plotted against deformation between pin and plate (about 3 pin diameters away) is three times the initial slope.

Because of the early local yielding and associated stress redistribution, mathematical formulas for maximum local stresses based on the assumption of elastic behavior have doubtful utility in the actual design of pin-connected steel plates under steady loads. For non-ductile materials, or for ductile materials designed for repeated stress, the elastic stress distribution is of importance. An approximate mathematical solution by J. Beke[4] has been applied to experimental tests of large pin-connected members in the Hugo-Preuss Bridge, in Berlin, Germany.[5]

Beke's formula is based on the simplest possible assumptions and is applicable in the elastic range. More exact solutions become increasingly complex and, in any case, give little indication as to the actual load carried at the general yield point or ultimate. To have practical value, a mathematical solution should be based on the theory of plasticity, and should include the study of the phenomenon of plastic "dishing" of thin plates. The solution of this problem has not been attempted in the present investigation. Of first importance to the designer are the answers to the questions: "How much load will a structural unit carry without excessive deformation?" and "What is its strength at failure?" In the present instance, the answer is given in the form of empirical equations, validated by a wide range of tests, and concerned with average stresses at general yield and ultimate. The large number of relatively thin plates tested give information on the greatly reduced margin between general yield and ultimate which is caused by the "dishing" type of failure in laterally unrestrained plates.

TEST PROGRAM AND PROCEDURE

The program of 106 tests was designed to cover the critical range of variables. The same size of pin, 3 in. in diameter, was used in all tests. The four variables ranged as follows: (1) Plate thicknesses varying from $\frac{1}{8}$ to $\frac{3}{4}$ in.; (2) plate widths of 6, 8, and 10 in.; (3) edge distance behind pinhole varying from 1 in. to 3.2 in.; and (4) pin clearance varying from a tight fit to 0.2 in.

FIG. 2.—APPARATUS FOR TESTING PIN-CONNECTED STEEL PLATE LINKS

The material specified was Universal Mill Plate with rolled edges, a medium grade structural steel free from rust. All the plates of similar width and thickness were cut from the same stock with an additional section cut for tensile test coupons. The ends of the specimens were flame-cut to a length an inch or more longer than required, and were cut at the testing laboratory by hacksaw to the exact length. Two tensile coupons cut parallel with the axis of rolling and two cut transversely were made from each plate series, the results being given in Table 2.

The arrangement of the apparatus used during a typical test is shown diagrammatically in Fig. 2, and by photograph in Fig. 3. The upper pin-holder

passed through the upper fixed head of the testing machine where it engaged transverse bars by means of lugs which allowed freedom of motion of the holder. The lower holder passed through the moving head of the testing machine and was open at the side to allow observation of the test. The upper end of the test specimen was blocked by plates on either side to ensure failure at the lower pinhole. The holders were built entirely by flame-cutting and welding steel slabs.

‡ Corners clipped at 45 degrees.

Four different observations were made at successive loads during each test, as follows:

(1) Longitudinal deformation between pin and plate was measured by two Ames dials $\left(\frac{1}{10\,000}\right)$ attached rigidly to arms which were fixed to the pins by set screws as shown in Fig. 2. The plungers of these dials engaged bars at-

tached to the test pieces by pointed screws about 8.5 in. from the center of the lower pin. The graph of the longitudinal deformation, plotted as abscissa with the load as ordinate, was used as a basis for determining the general yield point of the links. The point of general yield was taken as the load at which the slope of the load-deformation curve was three times that in the elastic range.

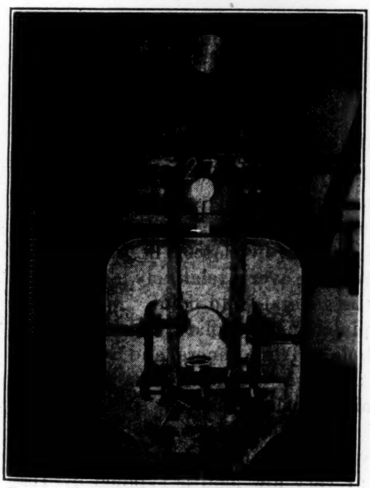

FIG. 3.—GENERAL VIEW OF TEST ARRANGEMENT, WITH DIALS PLACED TO DETECT "DISHING"

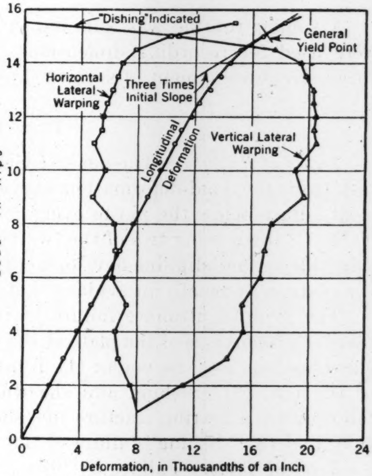

FIG. 4.—LOAD-DEFORMATION GRAPHS FOR TEST NO. 5

(2) Five Ames dials fixed to two main arms and one cross-piece engaged the lower surface of the test piece in order to measure any lateral movement

which would indicate the beginning of "dishing." The arms for holding these dials were fixed rigidly to the center of the test specimen, the arrangement being shown in Fig. 2. There were three points along two vertical lines, therefore, and three across the lower face of the plate. A study of these dial readings during successive load increments indicated any lateral movement along these three lines.

(3) Strains in the pin-plate material were measured along critical sections by means of Huggenberger tensometers, which were calibrated by an interferometer device designed and built by Raymond D. Mindlin, Jun. Am. Soc. C. E. The tensometers served two functions: (1) To obtain the stress distribution across the net section within an elastic range; and (2) to detect stress redistribution as indicated by variations in the slope of the strain curves. This, of course, does not necessarily indicate that the limit of proportionality had been exceeded at the exact point where the strain is measured. The tensometers were also used in determining the modulus of elasticity of the steel in the tensile coupon tests.

(4) The surface slip lines which are visible in the mill scale of structural steel at points of over-strain were accentuated by coating the surfaces of the plate at the lower pinhole with whitewash. The progress of the slip lines was recorded during successive load increments, and photographs were taken of all typical patterns. The whitewash consisted of 35 grams of hydrated lime mixed with 50 cu cm of water.

A similar routine was followed in all the tests, and mimeographed forms were used for recording dimensions, dial and tensometer readings, and the successive development of surface slip-lines.

Test Results

Types of Failure.—The general yield point, arbitrarily determined in every test from the load-deformation curve, was preceded by surface evidence of local failure below the pin in every instance except Tests Nos. 75 and 77 (see Table 1), these being two of the twelve tests of narrow plates 6 in. wide. Considerable surface slip-line development, extending over a relatively large area of the plate, was usually in evidence before the general yield point.

The type of ultimate failure in the pin-connected plate depends on the relative proportions of the plate at the pinhole. Three general and overlapping classifications may be made: (1) Tension failure in the net section at one side of the pin; (2) crushing and shearing failure below the pin, in some cases followed by a tearing fracture in "hoop" tension after considerable deformation; and (3) "dishing" failure of thin plates which are laterally unrestrained.

Typical Tests.—Failure by "dishing" at very low load is typified by Test No. 5, Table 1. The load-deformation curve, to determine the general yield point, and the curves of lateral and vertical warping indicative of "dishing" are shown in Fig. 4. A photograph of the surface slip-line pattern after "dishing" of Test No. 5 is shown in Fig. 5. This plate "dished" at a load of only 1 200 lb above the general yield point, and, in such cases, the slip lines appeared only on the convex surface. The "dishing" itself is not evident in this side view,

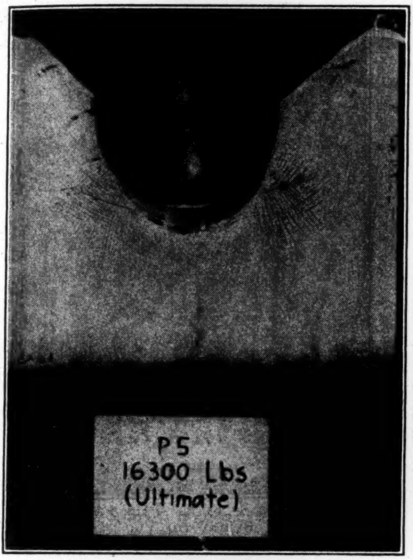

FIG. 5.—TEST NO. 5 AFTER FAILURE BY "DISHING"; SHOWING SLIP-LINES ON CONVEX SURFACE

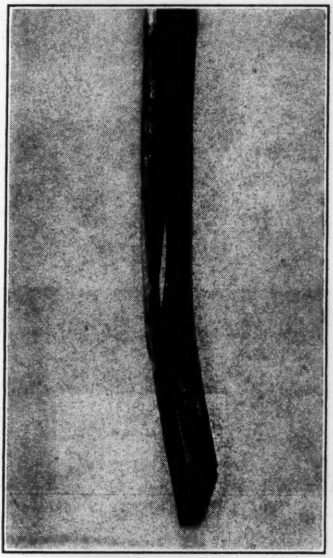

FIG. 6.—SHAPE OF TEST PIECE AFTER FAILURE BY "DISHING"

but is clearly indicated in Fig. 6, showing the shape of the plate after complete failure by "dishing."

The test of Plate No. 32 is typical of failure behind the pinhole, due to insufficient edge distance, *a*. Fig. 7 gives the load-deformation curve for this test and shows sketches similar to those taken in every test to record the progressive growth of surface slip-lines. Fig. 8 illustrates the further spread of the surface slip-lines at a load of 26 kips, and Fig. 9 shows the fracture after failure. The condition of the whitewash in Fig. 9 shows the completely plastic region below the pin prior to failure and the relative absence of surface slip-lines along the sides and above the pinhole. Fig. 10 shows an end fracture in another test of more balanced design and greater plastic elongation. Fig. 11 shows a surface slip-line pattern near the ultimate strength in

FIG. 11.—TEST NO. 35 AT 40 KIPS AND JUST PRIOR TO "DISHING"

Plate No. 35, similar to Plate No. 32, but of more balanced design. This plate was the same in every respect as Plate No. 32 with the exception of greater edge distance, *a*, with the result that considerable local crushing below the pin developed before the final spread of the slip-lines. The slip-lines indicated in Fig. 11 were duplicated on both sides of the plate. At a load of 41.5 kips, the plate "dished" causing a slip-line pattern similar to that in Fig. 5 to be superposed on the convex side. Unlike Test No. 5, however, Plate No. 35 was thick enough to develop considerable reserve strength between the general yield stress and ultimate failure by "dishing."

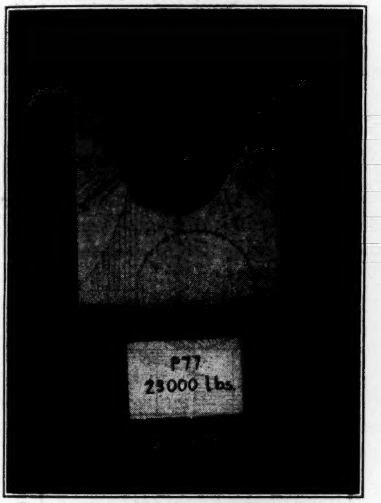

FIG. 12.—TEST NO. 77 AT 23 KIPS, SHOWING YIELDING AT THE SIDE

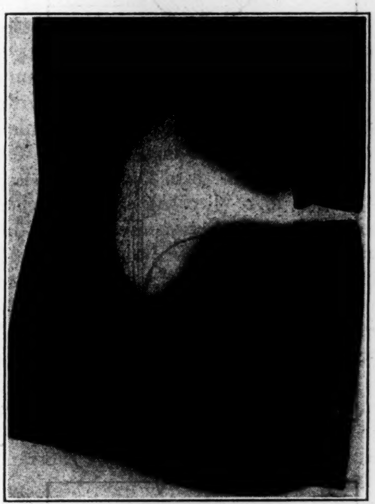

FIG. 13.—TEST NO. 82 AFTER FRACTURE AT SIDE OF PINHOLE

With one exception the series of plates which were 6 in. wide failed either in the net section in tension, or by "dishing." Fig. 12 shows the slip-line pattern soon after the general yield point of a 6-in. by $\frac{3}{16}$-in. plate prior to ultimate failure by "dishing," and Fig. 13 shows the side fracture, at ultimate strength of a 6-in. by $\frac{1}{2}$-in. plate.

Stress Distribution.—The stress distribution in the plate around the pinhole is complex, and may best be studied within the elastic range by means of photo-elastic tests. Complete studies of the stress pattern and distribution in a plate around a pinhole have been made by previous investigators.[6]

The maximum stresses are the localized contact compressive stresses at the point of bearing of pin on plate, and the concentration of tensile stress at each side of the pinhole. Except in the case of tight-fitting pins, the localized contact stresses produce the first surface evidence of local yielding. For a discussion of the subject of contact stresses reference may be made to an in-

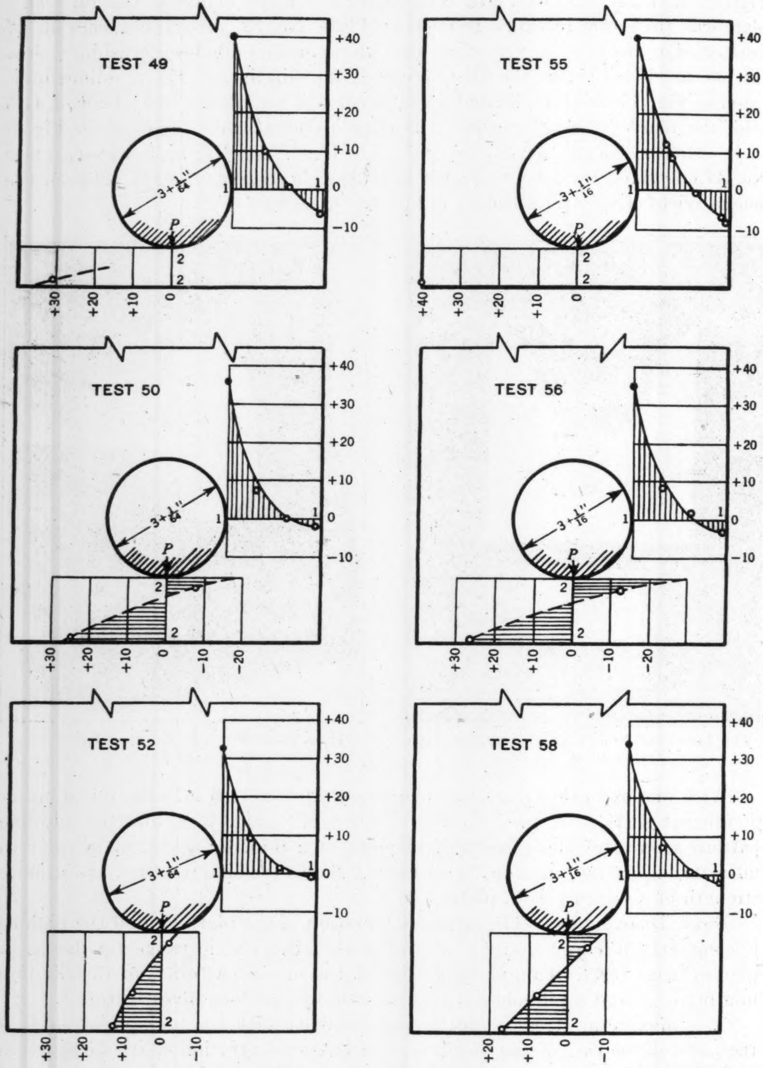

FIG. 14.—STRAIN TIME MODULUS OF ELASTICITY NORMAL TO THE HORIZONTAL AND VERTICAL LINES BY TENSOMETERS ($P = 20$ KIPS)

vestigation of stresses under bridge rollers reported[7] in 1936, by V. P. Jensen, Assoc. M. Am. Soc. C. E.

Insufficient clearance around the pin made it impossible to place tensometers for measuring strains at the exact locations of maximum stress. The tensometers were useful in all tests, however, in detecting initial stress redistribution which indirectly determined loads at which local yielding had occurred at points of maximum stress. Additional tensometers were used in some of the tests to determine the strain distribution along vertical and horizontal lines (see Fig. 2). The results are indicated in Fig. 14 for six tests on 8-in. by 0.5-in. plates with a varying distance, *a*, and two different pin clearances. The values indicated in Fig. 14 are the products of the strain in one direction multiplied by the modulus of elasticity, and are not true stresses, although very nearly so along Line 1–1, where the normal horizontal stresses are negligible. The maximum value of the vertical strain times the modulus of elasticity, *E*, normal to Section 1–1 adjacent to the pin was determined indirectly by extending from the measured values a stress area that would be in equilibrium with the known total load on the section. The contact stresses below the pin vary rapidly and could not have been measured satisfactorily over the half-inch gage length available in a Huggenberger tensometer, even if clearance had been available. The strains normal to the vertical section, 2–2, were measured at as many points as possible and the products of these strains and the modulus of elasticity, *E*, are also indicated in Fig. 14. The true stresses normal to Section 2–2 in the vicinity of the pin are considerable larger than the values of strain times the modulus of elasticity, *E*, because of the unmeasured contact stresses.

It is important to note that considerable local yielding, either below or to the side of the pinhole, was always evidenced before the general yield point of the plate was noted, and that stress concentrations had little effect upon the ultimate strength.

Pin Clearance.—A special series of tests was made in which clearance between pin and pinhole was the only variable. The load-deformation curves were extended far beyond the general yield point in these tests and three typical curves are shown in Fig. 15. The results of this series of tests are discussed in the general "Summary of Test Results" which follows.

Summary of Test Results.—Table 1 presents an abbreviated summary of the results of all the tests. A detailed explanation of the various columns in this table follows: Columns (1), (2), (3), and (4) give measured dimensions of the specimens before test, at the end near the observed pinhole, based on the average value of micrometer readings made to the nearest 0.001 in.

Column (5) indicates the load at which the first surface slip-line was noted, together with its location and type. The first letter, *B* or *E*, indicates whether the line was below or to one side of the pin. The second letter (*S* or *C*) indicates whether the flaking was a definite line, indicating slip or shear along a certain path, or general flaking below the pin, indicative of compression yield by crushing (see Fig. 11 for illustrations of both types). In this column, of which only a qualitative interpretation may be made, the trend of the lowest noted loads is most nearly correct, since the whitewash at times had enough cohesion to remain in place after yielding had commenced.

---

[7] *Bulletin*, Iowa Eng. Soc., Vol. XI, No. 4, October, 1936, p. 9.

Column (6), Table 1, gives the load at which surface indication of failure had become general. By this is meant either the presence of several lines extending from the pinhole through to the end or side of the plate, or a general network of lines developed in the vicinity of the pinhole. The same qualifications must be made regarding interpretation as in the case of Column (5). Column (7) gives the first indication of general stress redistribution due to local yielding, either to one side (E) or below (B) the pinhole. The noted load in each case is the limit of proportionality of the tensometer readings plotted against load.

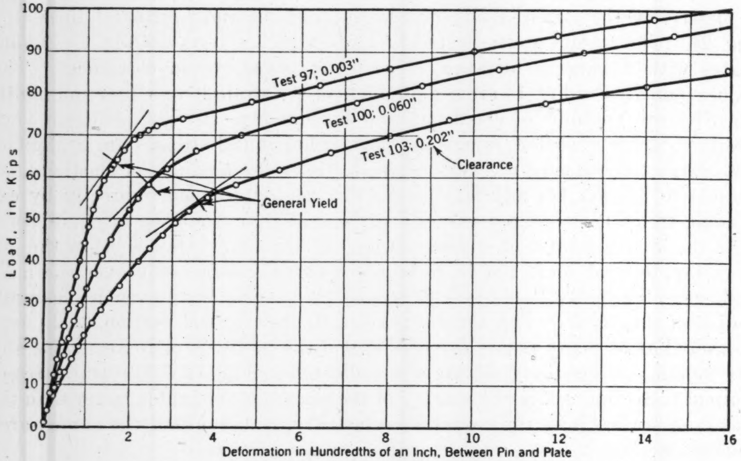

FIG. 15.—LOAD-DEFORMATION CURVES WITH PIN CLEARANCE AS THE ONLY VARIABLE

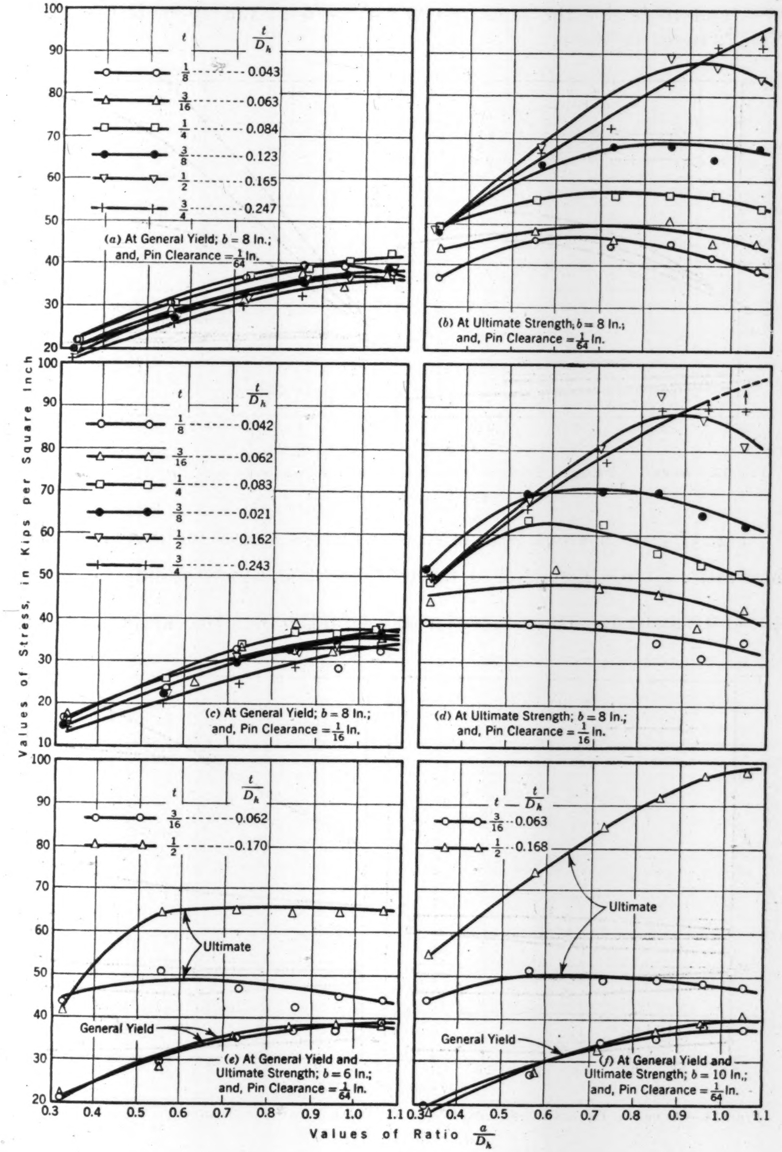
Column (8), Table 1, gives the load at the arbitrarily determined "general yield" strength at which point the longitudinal deformation between pin and plate was progressing at three times the initial rate; Column (9) indicates load at the start of "dishing," as detected by the limit of proportionality of the differences between the readings of the lateral dials, plotted against load; Column (10) gives the maximum load either at fracture or "dishing," in the latter case, just prior to large falling off of load during the progress of "dishing."

In Tests Nos. 49 to 106, the set readings were taken at five or more different load intervals to give a complete curve of set plotted against load. These data are omitted to conserve space but the permanent set in all tests followed closely the curve indicated in Fig. 19(b).

Graphical Summary of Test Results.—Average bearing stress at the general yield point, and the ultimate strength for the plates 8 in. wide (Tests Nos. 1 to 72) are plotted in Figs. 16(a) to 16(d), with the ratio, $\frac{a}{D_h}$, as abscissa. Figs.



(a) At General Yield; $b = 8$ In.; and, Pin Clearance $= \frac{1}{64}$ In.

(b) At Ultimate Strength; $b = 8$ In.; and, Pin Clearance $= \frac{1}{64}$ In.

(c) At General Yield; $b = 8$ In.; and, Pin Clearance $= \frac{1}{16}$ In.

(d) At Ultimate Strength; $b = 8$ In.; and, Pin Clearance $= \frac{1}{16}$ In.

(e) At General Yield and Ultimate Strength; $b = 6$ In.; and, Pin Clearance $= \frac{1}{64}$ In.

(f) At General Yield and Ultimate Strength; $b = 10$ In.; and, Pin Clearance $= \frac{1}{64}$ In.

FIG. 16.—AVERAGE BEARING STRESSES CORRESPONDING TO VALUES OF THE RATIO, $\frac{a}{D_h}$.

16(*e*) and 16(*f*) give the same results for the 6-in. and 10-in. plates, Tests Nos. 73 to 96, inclusive.

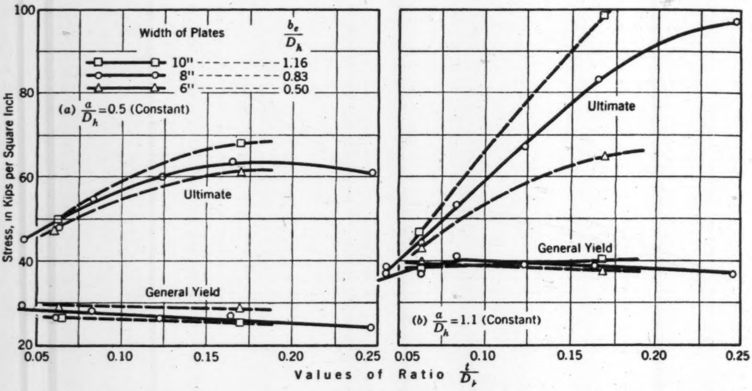


FIG. 17.—AVERAGE BEARING STRESSES AT THE GENERAL YIELD POINT AND ULTIMATE STRENGTH, WITH VARYING RATIO, $\frac{t}{D_h}$

Fig. 17 gives average bearing stresses plotted against the variable thickness ratio, $\frac{t}{D_h}$, for Tests Nos. 1 to 96, Table 1, and for two different ratios, $\frac{a}{D_h}$, of 0.5 and 1.1. The values plotted were taken from the curves in Fig. 16.

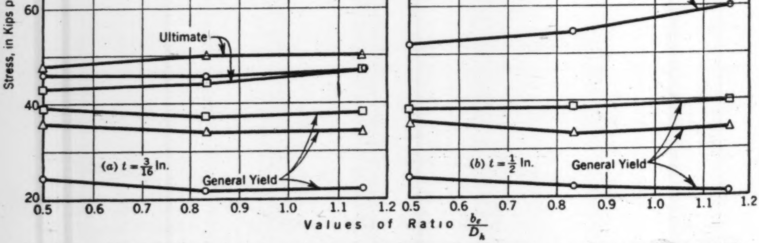

FIG. 18.—AVERAGE BEARING STRESSES AT THE GENERAL YIELD POINT AND ULTIMATE STRENGTH, WITH VARYING RATIO, $\frac{b_e}{D_h}$

In Fig. 18 the average bearing stress is plotted against the ratio, $\frac{b_e}{D_h}$, as abscissa for all the tests of $\frac{3}{16}$-in. and $\frac{1}{2}$-in. plates.

Fig. 19(*a*) gives the average bearing stress at the general yield point and ultimate strengths for Tests Nos. 97 to 106 (Table 1), in which the pin clearances are the variable, and are plotted as abscissa. Fig. 19(*b*) shows the relation between permanent set and variable pin clearance for the same series at different bearing stresses and at the general yield.

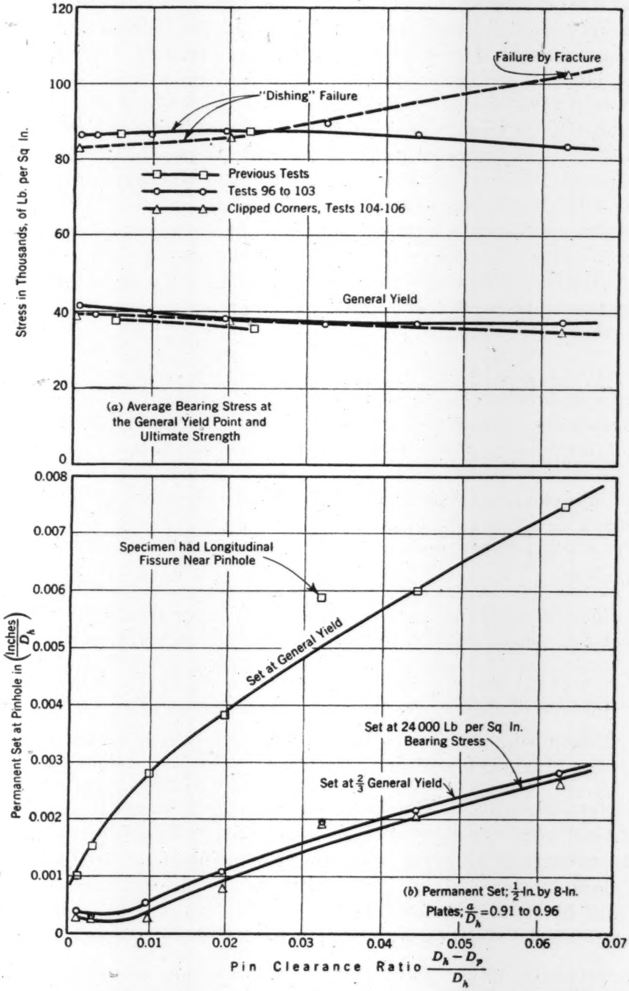

FIG. 19.—EFFECT OF VARIATIONS IN THE PIN-CLEARANCE RATIO, $\frac{c}{D_h} = \frac{D_h - D_p}{D_h}$

RELATION OF TEST RESULTS TO DESIGN

This paper includes no recommendations as to proper working stresses, factors of safety, or allowable permanent sets, which are properly the subject of specifications set up by engineering groups. In the following text, empirical formulas are presented for predicting the average bearing stress at the general yield and ultimate strength of pin-connected plate links similar to those tested. In order to study the four variable dimension ratios which affect the strength of the plates in the regions of greatest variation, many of the test pieces have dimensions outside the usual range of design. As possible design proportions are approached, however, the test results show a uniformity of trend which warrants the application of the formulas to all usual design proportions. Definite limits within which the formulas are applicable are noted in connection with each. The formulas agree closely with the average test results; and, in case of variation of more than a small percentage, they are adjusted to agree with the lowest trend of test results. In applying these formulas to design, these further restrictions are emphasized:

(1) Material should be structural grade steel for bridge work as covered by standard specifications.[8]

(2) Loads are static and pins do not rotate. For repeated stress conditions or for rotating pins appropriate allowances must be made.

(3) No rivet or bolt-holes may be drilled or punched in the vicinity of the pinhole. Previous tests[2] have noted the weakening effect of such small holes, either below or above the pinhole.

(4) The body of the plate shall have the same dimensions as the gross section at the pinhole.

Notation.—Reference should be made to Fig. 1 for the notation in regard to dimensions of plate. Ratios to which reference has already been made are:

$$\frac{t}{D_h} = \frac{\text{Plate thickness}}{\text{Pinhole diameter}}\,;\ \frac{b_e}{D_h} = \frac{\text{Edge distance to side of pinhole}}{\text{Pinhole diameter}}\,;$$

$$\frac{a}{D_h} = \frac{\text{Edge distance below pinhole}}{\text{Pinhole diameter}}\,;\ \frac{c}{D_h} = \frac{D_h - D_p}{D_h} = \frac{\text{Pin clearance}}{\text{Pinhole diameter}}\,.$$

The unit stresses are: s_{by} = average bearing stress between pin and plate at general yield of plate; s_{bt} = average bearing stress between pin and plate at ultimate strength of plate; s_y = tensile yield point of material as determined by standard tension test; and s_t = ultimate tensile strength of material as determined by standard tension test.

General Yield Point—The average bearing stress at the general yield point is not appreciably influenced by plate thickness ratios, $\frac{t}{D_h}$ greater than $\frac{1}{20}$, nor by the edge distance ratio, $\frac{b_e}{D_h}$, for values greater than $\frac{1}{2}$. The test data do not give results for $\frac{b_e}{D_h}$ greater than 1.2, but the bearing stress in such cases at the general yield point is probably not influenced greatly for values of $\frac{b_e}{D_h}$ within the usual range of design. The clearance between pin and pinhole, as defined by the ratio, $\frac{c}{D_h}$, has a minor effect on the general yield point, as indicated in Fig. 19(*a*). The general yield point of the plate is induced principally by a yielding of the material behind the pin. This yielding is preceded by a crushing failure below the pin which progresses until all the metal behind it starts to give way in a plastic state. In very thin plates the general yield is followed quickly by "dishing" and ultimate failure, whereas in thicker plates there is a large plastic reserve before ultimate failure occurs.

---

[8] Specification A7-34, Am. Soc. for Testing Materials.

The following formula gives the average bearing stress at the general yield point:

$$s_{by} = \frac{s_y}{2}\left[3\left(\frac{a}{D_h}\right) - \left(\frac{a}{D_h}\right)^2 - 2\left(\frac{c}{D_h}\right)\right] \dots\dots\dots\dots (1)$$

Equation (1) applies within the following limits:

$\frac{a}{D_h}$ between 0.3 and 1.2

$\frac{c}{D_h}$ between 0 and 0.07

$\frac{b_e}{D_h}$ greater than 0.5 (otherwise general yield will be entirely in net section)

$\frac{t}{D_h}$ greater than 0.05 (otherwise ultimate failure by "dishing" may precede any yielding)

Equation (1) is based on the test average of s_y equal to 39 kips per sq in. Based on the minimum specification requirement of 33 kips per sq in. for structural steel for plates, shapes, and bars in bridges (A. S. T. M. A7–34) and using ratios of $\frac{a}{D_h} = 1.2$ and $\frac{c}{D_h} = \frac{1}{250}\left(\frac{1}{50}\text{-in. clearance for a pin 5 in. in diameter}\right)$, by Equation (1), s_y is 35.4 kips per sq in. If a factor of safety of 1.5 were suitable with respect to the general yield point, the allowable working stress would be 23.6 kips per sq in., which corresponds closely with the frequently specified allowable stress of 24 kips per sq in. If such a working stress is suitable, it should only be used when the plate is thick enough to prevent ultimate failure at a low load by "dishing." The tests will be examined later to develop criteria of proportions which will insure against "dishing" failure and at the same time give a balanced design.

Ultimate Failure.—The three general types of ultimate failure have been described previously (see heading, "Test Results: Types of Failure"). Three empirical formulas (in close agreement with test results) will be presented to serve as indices of the average bearing stress at the ultimate strength in the case of failure by any of the three types. Applied to a plate of any proportions, the lowest value obtained from the three equations indicates the expected ultimate strength and the type of failure. All the equations are written in terms of average bearing stress between pin and plate, as follows:

Failure by fracture at side of pinhole,

$$s_{bt} = 2s_t\left(\frac{b_e}{D_h}\right) \dots\dots\dots\dots\dots\dots\dots\dots (2)$$

Failure by fracture below pinhole,

$$s_{bt} = s_t\left[1.13\left(\frac{a}{D_h}\right) + \frac{0.92\left(\frac{b_e}{D_h}\right)}{1 + \left(\frac{b_e}{D_h}\right)}\right] \dots\dots\dots\dots\dots (3)$$

Failure by "dishing,"

$$s_{bt} = 20 + 315\left(\frac{t}{D_h}\right) + 75\left(\frac{tb_e}{D_h^2}\right) + 20\left(\frac{a}{D_h}\right) - 20\left(\frac{a}{D_h}\right)^2 \dots (4)$$

In correlating Equations (2) and (3) with the test results, the test coupon average of $s_t = 62$ kips per sq in. applies. In applications to design the minimum specification requirement for s_t should be used. The following limitations as to dimensions are made: $\frac{a}{D_h}$ between 0.3 and 1.2; and, $\frac{c}{D_h}$ between 0 and 0.07.

The first limitation automatically limits the other dimensions (whenever they are determining factors) to values close to the test range. The second limitation indicates the test range but does not enter the equations because the clearance was not found to influence the ultimate strength appreciably. Although $\frac{a}{D_h}$ varied from 0.325 to 1.05 in the tests, the extension to 1.2 is based on the fact that the test results approached a uniform trend in the upper limit of $\frac{a}{D_h}$. Further remarks on each type of failure follow.

Failure by Fracture at Side of Pinhole.—This type of failure occurred only in the 6-in. plates. The test results showed that the material in the net section did not fail until the average stress in that section reached the ultimate tensile strength of the material as determined by a standard tension test. This indicates that the stress concentrations near a circular hole, which exist in the elastic range, have no effect on the ultimate strength of structural steel under static loads.

Equation (2) simply states that if failure is by tension in the net section, the average stress through this section will be the same at failure as in the case of a standard tension test. The stress actually developed, based on original areas and a test average of $s_t = 62$ kips per sq in., was slightly higher than that determined by Equation (2), due probably to the fact that the lower stressed material above and below the minimum section did not allow so much "necking down" and reduction of area as in the case of the straight tensile coupons.

Ultimate Failure Below Pinhole.—A study of the plates that failed in this manner shows that the ultimate strength of the plate is dependent both on the material below and to the side of the pinhole, the results agreeing with Equation (3) for $s_t = 62$ kips per sq in.

Ultimate Failure by "Dishing."—Equation (4) is for plates unsupported laterally at the ends. If the plate is blocked securely against "dishing" at the end, either Equation (2) or Equation (3) may determine the ultimate strength. (Although no blocked plates were tested in the present investigation, this statement is verified by tests made on the pin-plates of the Quebec Bridge (see Table 3)). Equation (4) is not written in terms of s_t, as are Equations (2) and (3), because the "dishing" is primarily a function of stability rather than strength.

TABLE 3.—COMPARISON OF TEST DATA, MAUMEE BRIDGE AND QUEBEC BRIDGE

* D = "dishing"; F = fracture; B = below pin; and, E = side of pin.

† End of plate blocked to prevent "dishing."

Balanced Design.—Assuming that the plate is thick enough, or that it is blocked laterally, so as to prevent "dishing," a comparison of Equations (2) and (3) yields the following criteria for equal strength or balanced design with respect to the edge distances to the side and below the pin:

$$\frac{a}{b_e} = \frac{1 + 1.75\left(\frac{b_e}{D_h}\right)}{1 + \left(\frac{b_e}{D_h}\right)} \qquad \text{(5)}$$

Equation (5) gives a slight excess of a distance.

What plate thickness is required to prevent "dishing"? Assuming that the design is balanced in other respects according to Equation (5), the following thickness ratio, obtained from a comparison of Equations (2) and (4), gives the required minimum allowable thickness ratio, $\frac{t}{D_h}$:

$$\frac{t}{D_h} = \frac{-20 + 123\left(\frac{b_e}{D_h}\right) - 20\left(\frac{a}{D_h}\right) + 20\left(\frac{a}{D_h}\right)^2}{315 + 75\left(\frac{b_e}{D_h}\right)} \quad \ldots\ldots\ldots (6)$$

Although Equation (6) gives sufficient thickness to prevent "dishing" in an otherwise balanced design, it also gives more than sufficient thickness for plates which are not balanced according to Equation (5). The "dishing" is more nearly a direct function of the ratio, $\frac{a}{t}$, than $\left(\frac{t}{D_h}\right)$, and Fig. 20 shows the maximum allowable ratio, $\frac{a}{t}$, to prevent "dishing" for plates balanced in design according to Equations (5) and (6).

In general, the tests indicate that the most efficiently designed pin-plate connectors are those narrow in width, thick enough to prevent "dishing," and having material below the pinhole in the proportions specified by Equation (5).

Comparison with Previous Tests.—The results of two previous series of tests on pin-connected plates of larger dimensions than those of the present investigation are presented in Table 3. The second group of ten tests is taken from the report[2] on the Quebec Bridge. Six of these tests were models, using pins 5 in. in diameter, and the remaining four were full-sized hangers with 12-in. pins, and plate widths of 26 in. or 28 in. The results of these tests check well with the strengths predicted by Equations (2) to (4), only two of them falling below, with a maximum difference of about 4%, and the remainder above, by as much as 10% in some instances. The material used in these pin-plates had slightly higher ultimate strength than that used in the present study.

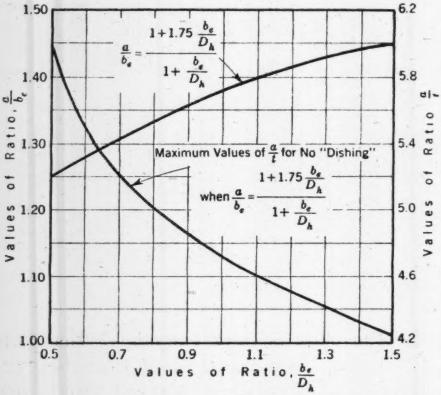

FIG. 20.—BALANCED DESIGN OF ULTIMATE STRENGTH[1]

The results of tests of eight pin-connected plates to determine the best design for anchorage bars for the Maumee River Suspension Bridge are also presented in Table 3. These bars had a reduced width in the main section between pinholes. All the test strengths of these bars fall below the values given by Equation (2), Equation (3), or Equation (4). Apparently, the reduced width in the body of the bar increased the tendency toward "dishing," and reduced their strength, although this may not necessarily be the cause. It is to be noted that the two tests with largest plate width in the body are only 7% less than the strengths indicated by Equation (5). Fracture failures below the pin were reported in these tests but this was combined at the same time, with "dishing." Since the exact dimensions of the specimens are not known and their number is limited, no final conclusion can be given in connection with these tests.

Illustrative Example.—Assume that clearance requirements make it necessary to use a pin-plate 1 in. thick to carry a load of 200 kips at a working stress in bearing of 24 kips per sq in. (A. S. T. M. Specification A7–34). The required pin diameter at 24 kips per sq in. $= \frac{200}{1 \times 24} = 8.33$ in., which dictates the use of a pin with a diameter of 8.5 in. The required net edge-distance at the pinhole, at 18 kips per sq in., is $b_e = \frac{200}{2 \times 1 \times 18} = 5.55$ in. With $b_e = 6$ in., this makes a total width of 20.5 in. required, and the ratio, $\frac{b_e}{D_h} = \frac{6}{8.5} = 0.706$. From Fig. 20, for balanced design: $\frac{a}{D_h} = 0.75 \times 1.31 = 0.985$, from which $a = 0.985 \times 8.5 = 8.4$ in. (use $a = 9$ in.). By actual measurement, $\frac{a}{D_h} = 1.06$; $\frac{t}{D_h} = \frac{1}{8.5} = 0.118$; and, $\frac{a}{t} = \frac{1.06}{0.118} = 9.0$, which is more than the 5.27 allowable maximum for no "dishing," for the ratio, $\frac{a}{D_h} = 1.06$, from Fig. 20. The plate, therefore, will fail by "dishing." By Equation (4), the average bearing stress at ultimate strength is, $s_{bt} = 20 + 315 \times 0.118 + 75 \times 0.118 \times 0.75 + (1.06 - 1.06^2)\,20 = 62.63$ kips per sq in. The ultimate strength is $62.63 \times 8.5 \times 1 = 532$ kips; and, the safety factor with respect to the ultimate $= \frac{532}{200} = 2.66$.

As an alternative, suppose that the plate is securely blocked to prevent "dishing." The ultimate strength will then be given either by Equation (2) for side failure, or by Equation (3) for end failure For $s_t = 60$, the minimum by A. S. T. M. Specification A7–34, Equation (2) gives $s_{bt} = 120 \times 0.75 = 90.0$ kips per sq in.; and, by Equation (3), $s_{bt} = 60 \left[1.13 \times 1.06 + \frac{0.92 \times 0.75}{1 + 0.75} \right] = 96$ kips per sq in. The ultimate strength, then, if the plate is blocked $= 90 \times 8.5 \times 1 = 765$ kips; and the factor of safety with respect to the ultimate $= \frac{765}{200} = 3.82$.

General Yield Point of Plate.—If a pin clearance is $\frac{1}{32}$ in., the pin-clearance ratio, $\frac{b_e}{D_h} = \frac{1}{32 \times 8.5} = 0.00367$. By Equation (1), the average bearing stress at the yield point will be: $s_{by} = 33\left[\frac{3 \times 1.06 - 1.06^2 - 2 \times 0.00367}{2}\right] = 33.8$ kips per sq in.; the total strength at the yield point = 33.8 × 8.5 × 1 = 288 kips; the safety factor with respect to the yield point = 1.44; and the permanent set for a stress of 24 kips per sq in. (from Fig. 19(*b*)) = 0.00025 × 8.5 = 0.002 in.

It should be noted that the general yield point may be raised by arbitrarily increasing the end ratio, $\frac{b_e}{D_h}$, but this will also increase the tendency to "dish." In cases where "dishing" is eliminated by suitable plate thickness or by side blocking, a low factor of safety with respect to the general yield point may be justified, in the opinion of the engineer, due to the high plastic reserve strength prior to ultimate failure.

Clipped Corners.—As indicated by previous tests and a very limited number of the present tests (three in all), the corners of the plate below the pin may be clipped with only slight loss of strength. It is recommended that 20% more net section be maintained on a 45° line through the corner than the minimum at the side or below.

SUMMARY

Within certain well-defined limits as to material and shape, this paper has presented empirical equations for predicting the general yield point, ultimate strength, type of failure, and balanced proportions of pin-connected steel plates. These equations agree closely with the 106 tests reported, in which the pin diameter was 3 in., and are further validated by tests on similar pin-connected links used in the erection of the Quebec Bridge in which the pin diameter was as much as 12 in. Although the results do not check well with a number of tests of pin-connected anchorage bars for the Maumee River Suspension Bridge, this may possibly be accounted for by reason of the reduced width in the body of these bars. Hence, the results of this paper are not intended to apply directly to pin-connected plates having the shape of standard eye-bars unless tests on such eye-bars show agreement with the present results.

ACKNOWLEDGMENT

The tests were conducted as a research project of the Department of Civil Engineering, of which James K. Finch, M. Am. Soc. C. E., is Executive Officer. The author is indebted for the close co-operation of the late Albin H. Beyer, M. Am. Soc. C. E., who was Director of the Testing Laboratories, and to the present Director, W. J. Krefeld, M. Am. Soc. C. E. Leon Krantz assisted in setting up the apparatus and operating the tests. The test program was originally suggested by Sterling Johnston, M. Am. Soc. C. E., and was conducted in co-operation with the American Institute of Steel Construction. Engineers of the American Bridge Company, the Bethlehem Steel Company, and the Chicago Bridge and Iron Works, contributed valuable criticism both as to the proper test program and the conclusions to be drawn from the results.

DISCUSSION

Harold D. Hussey,[9] M. Am. Soc. C. E. (by letter).—This paper is of much value in its field of structural design and especially in giving an empirical solution to a very complicated problem in buckling of plates; that is, the buckling of plates behind the pin in a pin-connected tension member. The tests which are reported were made on plain plates of uniform width and the author does not claim that his conclusions will apply to members of non-uniform width, such as eye-bars. The writer wishes to call attention, however, to some tests on eye-bars that agree very closely with the results obtained by Mr. Johnston.

When the width of the plate is given, the thickness required to prevent "dishing" can be determined from Equations (5) and (6) as follows: Let $\frac{a}{b_e} = M$; and, $\frac{a}{t} = N$. Solving for t,

$$t = \frac{M}{N} b_e \ldots\ldots (61)$$

Dividing both sides of Equation (61) by D_h and letting $\frac{t}{D_h} = t_D$; and, $\frac{b_e}{D_h} = b_D$:

$$t_D = \frac{M}{N} b_D \ldots\ldots (62)$$

Calculations show that the factor, $\frac{M}{N}$, has an approximate value of $0.3 \sqrt{b_D}$; therefore $t_D = 0.3\, b_D \sqrt{b_D}$; and,

$$t = 0.3\, b_e \sqrt{\frac{b_e}{D_h}} \ldots\ldots (63a)$$

Solving Equation (63*a*) for b_e,

$$b_e = 2.23\, t \sqrt[3]{\frac{D_h}{t}} \ldots\ldots (63b)$$

The value of a is determined from Equation (5).

The use of Equations (63*a*), (63*b*), and (5) will result in a design which has equal resistance to failure by fracture at the side of a pin-hole, fracture below a pin-hole, and "dishing." Specimens that failed by fracture at the side of a pin-hole did so at an average stress in that section equal to, or slightly higher than, the ultimate tensile strength of the material as determined by standard tensile tests. A common specification is that the net section through a pin-hole shall be at least 40% greater than the net section of the member.[10] This shows that standard design requirements are on the side of safety.

In the "Summary," the author states, "* * * the results of this paper are not intended to apply directly to pin-connected plates having the shape of standard eye-bars unless tests on such eye-bars show agreement with the present results." Records of tests of standard eye-bars which broke in the head are extremely rare because of the fact that eye-bars are usually made to certain minimum requirements, one of which is that the diameter of the pin shall be not less than seven-eighths the width of the bar.

[9] Designing Engr., Am. Bridge Co., New York, N. Y.

[10] A. R. E. A. Specification for Steel Railway Bridges, 1935.

Occasionally, however, eye-bars are made, which vary from standard practice, and they sometimes fail in the head. The latest case of this kind, to the writer's knowledge, occurred in 1931, when a 7-in. by 1-in. eye-bar was tested to destruction. The two heads were 16.5 in. in diameter and the pin-holes were 7 in. and 5.25 in. in diameter, respectively. The eye-bar failed by "dishing" and fracture in the head having the smaller pin-hole.

An analysis of this eye-bar head according to Equations (2), (3), and (4) indicates that failure should take place by "dishing." Solving Equation (4), $S_{bt} = 93.8$ kips.

This means that a 16.5-in. rectangular plate with the pin-holes in the two ends should have failed by "dishing" back of the 5.25-in. pin when the bearing stress between the pin and plate reached the foregoing value. The total tension on the plate would then be 492 450 lb. The eye-bar in question failed by "dishing" and fracture back of the 5.25-in. pin under a load of 492 000 lb (reading to the nearest kip), indicating agreement between this eye-bar test and the author's work. This is further verified by the fact that another eye-bar, which was a duplicate of the one noted, had been tested a few months earlier, and the failure had occurred in the body of the bar. This appears contradictory, but when it is noted that this eye-bar failed under a tension of 470 kips it is seen that the material failed just before the head of the eye-bar was about to fail by "dishing." These tests indicate that the author's results will apply to standard eye-bars.

If standard practice had been followed when making these eye-bars the minimum size of the pin would have been $6\frac{1}{8}$ in. in diameter (seven-eighths of 7 in.). A re-test of two more 7-in. by 1-in. eye-bars was made, but instead of using a 5.25-in. pin at one end the pin was made 6.25 in. in diameter in order to determine whether this increase would have any influence on the result. Both these eye-bars broke in the body of the bar, as would be expected from the author's results (a solution of Equation (4), using a 6.25-in. pin, shows that it would require a total tension of 520 kips to cause this head to fail by "dishing," whereas the eye-bars failed under tensions of 474 kips and 470 kips, respectively).

The author refers (in the "Introduction") to "forged" eye-bars. The writer wishes to emphasize that, although the two heads are produced by upsetting (or forging), the main body of the eye-bar is a plain rolled plate, or bar. For example, an eye-bar 65 ft from center to center of end pins has nearly 60 ft of rolled material with 4 ft to 5 ft at each end that has been forged. When a "forging" is specified, the material is manufactured to A.S.T.M. Specification A18, whereas A.S.T.M. Specification A7 gives complete requirements for annealed eye-bars. There is a considerable difference between these two materials. The latter specification is generally used for eye-bars, whereas the former never is; and when the term, "forged," is introduced, it leads to confusion.

BRUCE G. JOHNSTON,[11] ASSOC. M. AM. SOC. C. E. (by letter).—The discussion presented by Mr. Hussey is entirely constructive in nature. The close agreement between the tests of two eye-bars and the strength and type of failure predicted by Equations (2), (3), and (4) is very gratifying. It is unfortunate that these are the only two tests of eye-bars brought to light in discussion. Equations (63*a*) and (63*b*), used with Equation (5), will give a well-balanced design entirely safe with respect to failure by dishing. Equations (2), (3), and (4) should be used when close clearances or other special requirements make a balanced design impossible.

In connection with the application of this paper to the design of eye-bars it has been brought to the writer's attention that Section 411 of the A. R. E. A. Specification for Steel Railway Bridges has been changed to recommend a maximum net width-to-thickness ratio at the pin-hole of 8 instead of 12.

The writer wishes to express his appreciation to Mr. Hussey for his courtesy in discussing the paper.

WATER-HAMMER PRESSURES IN COMPOUND AND BRANCHED PIPES

BY ROBERT W. ANGUS,[1] ESQ.

WITH DISCUSSION BY MESSRS. K. J. DEJUHASZ, HAROLD A. THOMAS, F. KNAPP, MARTIN A. MASON AND PIERRE F. DANEL AND ANTOINE CRAYA, A. A. KALINSKE, AND ROBERT W. ANGUS.

SYNOPSIS

In two previous papers,[2, 3] the writer has derived the principal equations for water hammer and has given the theory in some detail, so that only the barest outline of the general theory is given herein. Beginning with the two general equations derived by L. Allievi,[4] a graphical construction has been explained in some detail and illustrated in two simple problems of uniform pipes.

For the application of the method to simple pipes, the reader should consult the earlier papers, as this paper deals with other problems, and particularly those on compound and branched pipes. Illustrations are given of the application to parallel pipes, pipes with dead ends, surge tanks in systems, pipes leading from reservoirs and having two branches, each discharging water, the effect of gate closure on turbines and draft-tubes, and the case of a pumping system in which the pressure falls so low as to cause the column to separate. In all these cases the variation of pressure and velocity with time is found for various points in the system.

All these problems, and many more, may be solved by a careful worker, both accurately and quickly, on the drafting-board, although their solution by analytical means is almost impossible.

Notation.—The letter symbols used in this paper are defined where they are first mentioned and, for convenience of reference, a complete list is given in the Appendix.

NOTE.—Published in January, 1938, *Proceedings*.

OUTLINE OF GENERAL THEORY

When a closed pipe is filled with moving liquid (water will be referred to hereafter), the laws governing the changes of pressure and discharge will depend upon the conditions under which flow occurs. If the motion is steady (by which is meant that the volume per second passing through any section of the pipe remains constant as time goes on), the Bernoulli equation may be applied.

When the motion is unsteady (that is, when the discharge at each section is varying from one instant to the next), the Bernoulli equation no longer serves, and the pressures and velocities are not connected by this equation. Sometimes during unsteady motion there is a mass flow of the entire column of water in the pipe, such as occurs when the water surges back and forth between two reservoirs, or between a reservoir and a tank; such cases are common and there must be an open tank or reservoir, or an air chamber, in the line.

On the other hand, variable motion may occur in a fully closed system provided there is anything to start it, the motion being then due to the elasticity of the water and pipe. Thus, variable motion may occur in a section of a pipe system with a "dead end," due to some change in the system, such as the closing of a valve somewhere, although there may be no delivery of water through the pipe.

The three cases are distinct and important: The first is used, for example, in finding the size of a pipe for given service; the second case is common in water-power plants where surge tanks are necessary to store and restore the water during load changes; and, the third case is of common occurrence in all systems. Quite frequently, the latter two cases occur together; there is a mass surge of the water in the system, but at the same time the elasticity of the water and pipes produces independent action, often building up high pressures at different points and not infrequently producing pressures at the bottom of an open tank many times greater than that corresponding to the depth of water in the tank. Under certain conditions, too, the elasticity of the water and pipe walls induces extremely low or collapsing pressures, and may even cause separation of the water column itself.

This paper refers to the latter case of unsteady motion which produces the phenomenon of water hammer. It will be best to start with the simple case of a horizontal uniform pipe connected at one end to a reservoir that has a fixed level and terminating in a nozzle, gate, or valve (the three terms are used in the paper for the same type of device) which may be used to control the flow. The equation of continuity is used and will be specifically applied to branch pipes, but it is to be noted that at a given instant the elasticity of the water and of the pipe walls enables the discharges at different points on the same pipe to differ at the same time.

In many problems, velocity head is relatively small, as is also friction loss, and the cases under consideration are simplified if the two terms are omitted; the pressures computed when friction loss is omitted are nearly always greater than the actual pressures and, therefore, the results are on the safe side. Where pipes burst, or in other unusual conditions, both friction and velocity may have to be taken into account, and the method of doing this is explained subsequently. For convenience, the reservoir level is assumed constant, although variations in it are easily allowed for; these variations are very slow, however, in comparison with the pressure wave velocity.

The case described is illustrated by Pipe $A\,B\,C$ of length L in Fig. 1, in which Point A is at the discharge end, Point C, at the reservoir end, and Point B, at the center. Under conditions of steady flow with the gate fully open, H_0 will represent the pressure on the gate as well as the elevation of the water surface above the gate, and if the pipe area is A_a, the steady velocity, V_0, in the pipe with the discharge, Q_0, is given by,

$$Q_0 = A_a\,V_0 \dots\dots\dots\dots\dots\dots\dots\dots (1)$$

in which the units are in feet and seconds. Suppose, now, that a closing movement of the gate is begun which would effect complete closure in T sec; any law of closure may be used, but if it is such that the "effective gate area" (by which is meant the actual gate area multiplied by the proper coefficient of discharge) decreases at a uniform rate with time, the motion is referred to as "straight-line" or "linear," a nomenclature used in the remainder of this paper.

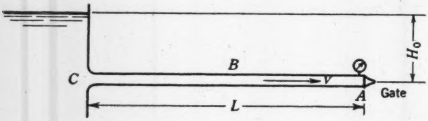

FIG. 1

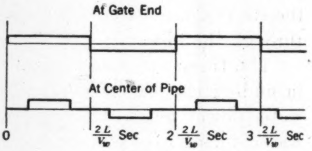

FIG. 2

The actual gate movement may be assumed made in small steps, each one of which causes a small change in the pipe velocity with a corresponding pressure change along the pipe. The mechanics of the phenomena are fairly well understood and need not be repeated, except to state that the first movement causes a direct pressure wave to travel up the pipe with velocity V_w, the round trip of this wave requiring $\dfrac{2\,L}{V_w}$ sec, and it returns a second time up the pipe from the gate as an indirect pressure wave unchanged in magnitude, etc. These waves continue to follow one another, each small gate movement producing corresponding waves, the ultimate pressure at any point being the resultant of those due to the separate waves. Fig. 2 illustrates what is meant by each wave, and its effect at the end and center of the pipe.

The magnitude of the pressure waves at the gate may be determined from the following considerations: After a small closing movement of the gate, a pressure wave travels up toward the reservoir with velocity, V_w, and in the time, δT, it will have traveled a distance (see Fig. 3),

$$L_w = V_w\,\delta T \dots\dots\dots\dots\dots\dots\dots\dots (2)$$

the pressure rise for such change being indicated by δh. Denoting the part of the velocity extinguished in this movement by δV, Newton's second law gives,

$$- w\, A_a\, \delta h = \frac{m\, \delta V}{\delta T} = \frac{A_a\, w\, V_w\, \delta T}{g} \frac{\delta V}{\delta T} \quad \ldots\ldots\ldots\ldots\ldots (3)$$

in which m is the mass of the water changed in velocity; and w is the weight of a cubic foot of water. The minus sign appears in Equation (3) because an increase in δh corresponds to a decrease in δV. The formula reduces to,

$$- \delta h = \frac{V_w}{g} \delta V \quad \ldots\ldots\ldots\ldots\ldots (4)$$

Integration of Equation (4) gives, for the first interval:

$$h = H - H_0 = \frac{V_w}{g} (V_0 - V) \quad \ldots\ldots\ldots\ldots\ldots (5)$$

in which H is the new reading of the gage at the gate. The maximum value of h results when $V = 0$; in other words, when the entire velocity is extinguished in the first interval, in which case the pressure rise is,[5]

$$h = H - H_0 = \frac{V_w}{g} V_0 \quad \ldots\ldots\ldots\ldots\ldots (6)$$

and this shows the interesting fact that the maximum pressure rise is independent of the dimensions of the pipe and of the head, and depends only on the velocity extinguished.

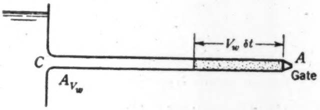

FIG. 3

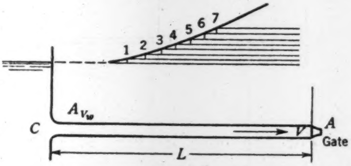

FIG. 4

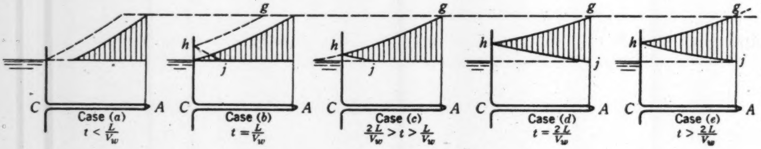
Since Equation (6) refers to the direct waves and takes no account of the reflected ones, it can only be applied to find the direct change in pressure corresponding to an individual gate movement and not to find the pressure rise in the pipe, directly, unless closure is effected in one interval, in which case no reflection occurs. The equation applies naturally within any interval provided the proper velocities are used. The magnitude of the direct wave in the nth movement of the gate will be indicated by F_n and is given by,

$$F_n = H_n - H_{n-1} = \frac{V_w}{g} (V_n - V_{n-1}) \quad \ldots\ldots\ldots\ldots\ldots (7)$$

Having traced the course of events following the first gate movement, it is now possible to see what happens during subsequent movements. If the closing time, T, is less than $\frac{L}{V_w}$, the events are as shown in Fig. 4, where the numbers indicate the pressures computed from Equation (5) corresponding to the small movements of the gate; the combined series of movements produces a wave of sloping (curved) front traveling first from the gate, and this wave will reach its maximum height before its "toe" reaches Point C, as represented in Fig. 5(*a*). When the closure requires $\frac{L}{V_w}$ sec, the wave front is shown in Fig. 5(*b*), the wave front covering the entire length of the pipe; but, in Case 5(*c*) in which the closure time exceeds $\frac{L}{V_w}$, the returning opposition wave neutralizes some of the positive pressures and the maximum pressure is exerted on the pipe until Point g is above Point j. In Case 5(*d*) the maximum pressure is reached only, but does not remain, as the opposition wave front cancels it, whereas, in Case 5(*e*), the pressure is never as high as in the former cases. The maximum pressure reached is the same in Cases (*a*) to (*d*) where $T \overline{<} \frac{2\,L}{V_w}$ (provided the same velocity is extinguished at each step); but the quicker the closure the longer the time will be during which this maximum pressure continues.

---

[5] A summary of the work done by N. Joukowsky, of Moscow, in 1898, has been given in a paper entitled "Water Hammer" by Miss O. Simin, *Proceedings*, Am. Water Works Assoc., 1904, p. 341.



Case (*a*) $t < \frac{L}{V_w}$ Case (*b*) $t = \frac{L}{V_w}$ Case (*c*) $\frac{2\,L}{V_w} > t > \frac{L}{V_w}$ Case (*d*) $t = \frac{2\,L}{V_w}$ Case (*e*) $t > \frac{2\,L}{V_w}$

FIG. 5

For the case in Fig. 5(*e*) the same maximum pressure is not reached. Furthermore, it may be shown that for linear gate movement the curvature of the wave front is not great; it is convex to the horizontal axis as drawn, so that in such cases as those in Figs. 5(*b*), 5(*c*), 5(*d*), and 5(*e*), the total pressure rise has roughly a straight-line variation from zero at the reservoir to a maximum value at the gate, a fact also confirmed by many computations.

The general proposition may then be stated that the maximum pressure rise is produced for closing times equal to, or less than, $\frac{2\,L}{V_w}$; this is commonly referred to as sudden closure. For short pipes the closure may easily be too slow to produce the most serious results, but it is quite possible in the longer pipes, and, for this reason, it is frequently stated that the danger of damage from water hammer is greater in long pipes than in short ones; this statement, however, is true only in the sense that the time of closure to produce the worst results is often within the range of operation of the valves on long pipes.

FUNDAMENTAL EQUATIONS FOR VARIABLE FLOW IN CLOSED PIPES

In order to establish the fundamental relations, the variation in flow is considered to be due to closing a valve in a pipe line, thereby causing a decrease in the flow. The equations thus established apply equally well to a gate-opening.[4] The pipe is assumed to be of a uniform diameter, D, and a thickness, t; and the problem frequently occurs in one or the other of the two forms shown in Fig. 6. The former (Fig. 6(*a*), with the enlarged section in Fig. 6(*b*)) corresponds to closing a nozzle on the end of a pipe, whereas Fig. 6(*c*) represents a pumping line with a control valve, decreased flow being caused by closing the valve or by cutting off power to the pump. Elsewhere,[3] the writer has demonstrated that, at any point, situated a distance, x, from the gate (Case (*a*), Fig. 5) and at a time, T, after closure begins:

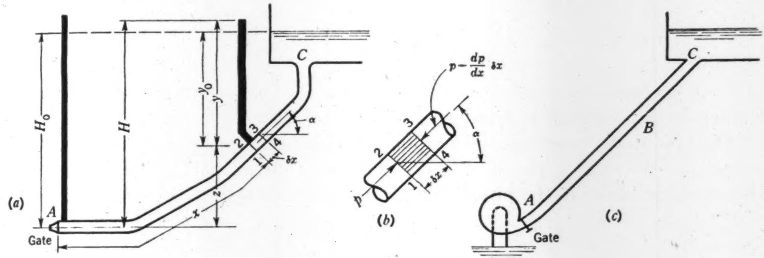


FIG. 6

$$\frac{\delta V}{\delta T} = g \frac{\delta H}{\delta x} \quad \text{(8a)}$$

and,

$$\frac{\delta V}{\delta x} = \frac{g\,\delta H}{V_w^2\,\delta T} \quad \text{(8b)}$$

In Case (*c*), Fig. 5, both left-hand members have a negative sign and, therefore, Equations (8) apply, with proper correction to the sign. Furthermore,

$$V_w = \frac{\sqrt{\frac{g\,K}{w}}}{\sqrt{1 + \frac{K\,D}{E\,t}}} = \frac{4\,665}{\sqrt{1 + \frac{K\,D}{E\,t}}} \quad \text{(9)}$$

in which K is the bulk modulus of elasticity for water; and, E is Young's modulus for the material in the pipe. Some approximate values of the ratio, $\frac{K}{E}$, are:

Steel plate	0.0097 (usually assumed as 0.01)
Cast iron	0.02 to 0.022
Concrete	0.10
Wood	0.20

In Equations (8) and (9), $\frac{\delta V}{\delta T}$, $\frac{\delta H}{\delta x}$, $\frac{\delta V}{\delta x}$, and $\frac{\delta H}{\delta T}$, refer to changes in a small cylinder (1 2 3 4, Fig. 6(*b*)) situated a distance, x, from the gate. The general integrals of Equations (8) were first obtained by Allievi as follows:

$$H - H_0 = F\left(T - \frac{x}{V_w}\right) + f\left(T + \frac{x}{V_w}\right) \dots\dots\dots\dots\dots (10a)$$

and,

$$V_0 - V = \frac{g}{V_w}\left[F\left(T - \frac{x}{V_w}\right) - f\left(T + \frac{x}{V_w}\right)\right] \dots\dots\dots (10b)$$

and the corresponding integrals for Case (*c*), Fig. 6, are similar except for the change in sign of the left-hand member in each case.

One point deserves special emphasis: The pressure head, H, is measured above the horizontal plane of the nozzle, so that at Section 1–2, Fig. 6(*a*), the actual pressure in the pipe is only y and is connected with H by the relation,

$$H = y + z \dots\dots\dots\dots\dots\dots\dots\dots (11)$$

The pressure rise at this section is $H - H_0 = y - y_0$; but the ratio of the pressures after, and before, gate movement is,

$$\frac{y}{y_0} = \frac{H - z}{H_0 - z} \dots\dots\dots\dots\dots\dots\dots\dots (12)$$

In Equations (10) (which will be referred to as Allievi's equations), H represents the pressure head, in feet, and V the velocity, in feet per second, at a point distant x from the gate, at a time, T, after closure begins; $F\left(T - \frac{x}{V_w}\right)$ denotes the sum of all direct pressure waves (positive, in closing), each persisting for a time, $T = \frac{2\,L}{V_w}$, at the gate; and $f\left(T + \frac{x}{V_w}\right)$ denotes the sum of all reflected pressure waves (negative, in closing), each of which quantities also persists for a time, $T = \frac{2\,L}{V_w}$ sec, at the gate. A little consideration will show that the direct wave in any interval is equal in magnitude, but of opposite sign, to the reflected wave, $\frac{2\,L}{V_w}$ sec later, if the reflected and direct waves each correspond to the same gate movement. This has been shown in the general discussion of the pressure waves in the pipe.

Allievi's equations (Equations (10)) may be used to find the conditions at any point on the pipe, but if the pressure at a point, $x = 0.75\,L$, is desired, the steps of the valve motion must be not more than $\frac{1}{4}\left(\frac{2\,L}{V_w}\right) = \frac{L}{2\,V_w}$ sec apart, and a similar statement applies to other points; for the gate the movements may be $\frac{2\,L}{V_w}$ sec apart. Similar equations may be written[2] where friction and velocity head are considered if the following quantity, H_T, is substituted for H:

$$H_T = H + \frac{V^2}{2\,g} + h_r \dots\dots\dots\dots\dots\dots\dots (13)$$

in which h_r is the friction loss, in feet, up to the point considered. The equations applying to Fig. 6(*a*) would then be:

$$H_T - H_0 = F\left(T - \frac{x}{V_w}\right) + f\left(T + \frac{x}{V_w}\right) \quad \text{.............} (14a)$$

and,

$$V_0 - V = \frac{g}{V_w}\left[F\left(T - \frac{x}{V_w}\right) - f\left(T + \frac{x}{V_w}\right)\right] \quad \text{......} (14b)$$

and for the case of Fig. 6(*c*) they are easily written. The solution of the problem is virtually the same whether H_T or H is used, and hence the graphs will be constructed using Equations (10).

The analytical method of dealing with water hammer has been used to some extent in practice. For example, Dr. Charles Jaeger[6] has described the analytical solution in considerable detail and has illustrated it by some examples. It must be evident, however, that: (*a*) Much care is to be exercised in its application; (*b*) some of the calculations are long and somewhat involved; and, (*c*) there is a possibility of error in using it unless one is doing it very frequently. It is quite difficult to apply in case of branched and complicated pipes, but has proved of great value in establishing basic relationships.

In order to simplify and hasten the answers to problems in water hammer, a number of graphical methods have been devised of which probably that of Allievi[4] was the first; but his method was only applied to uniform pipes, without friction, and usually with straight-line valve movement. Furthermore, the method is not practicable on account of the large scale to which the drawings should be made. Allievi used it to develop his useful series of charts. In 1926, Dr. Hans Kreitner[7] described a method of merit which was translated and summarized by the writer in 1935.[8] This method has been used by Hruschka.[9]

The construction described and applied in this paper is based on that of earlier writers, but its development is due very largely to Dr. O. Schnyder,[10] of Klus, Switzerland, and to Professor L. Bergeron,[11] of Paris, France, who have shown that the method is general and may be very simply used in solving the most complicated problems quickly.

GRAPHICAL METHOD

The graphical method proposed herein proceeds from Equations (10) and as these formulas are also used in the analytical development the same results will be obtained by the graphical as by the analytical solution. By addition and subtraction, they reduce to:

Bergeron, *Revue Generale de l'Hydraulique* (Paris), 1935, p. 12, etc.

$$H - H_0 = -\frac{V_w}{g}(V_0 - V) + 2F\left(T - \frac{x}{V_w}\right) \qquad \text{(15a)}$$

and,

$$H - H_0 = +\frac{V_w}{g}(V_0 - V) + 2f\left(T + \frac{x}{V_w}\right) \qquad \text{(15b)}$$

If Equations (15) are applied to the gate end of the pipe, where $x = 0$, they will be written:

$$H - H_0 = -\frac{V_w}{g}(V_0 - V) + 2F(T) \qquad \text{(16a)}$$

and,

$$H - H_0 = +\frac{V_w}{g}(V_0 - V) + 2f(T) \qquad \text{(16b)}$$

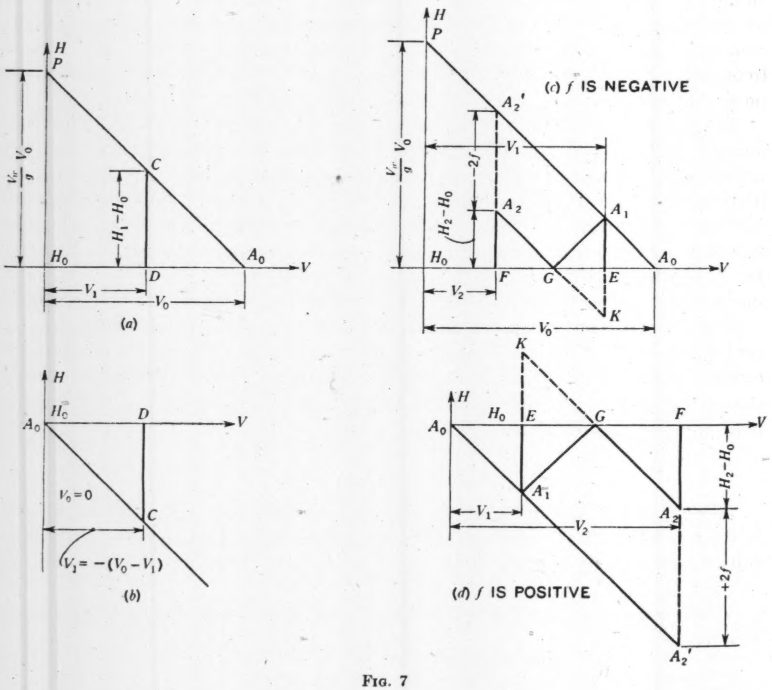

FIG. 7

In Fig. 7 the axes of H and V have been drawn as shown, and Point A_0 represents the initial steady velocity, V_0, and static head, H_0. In the first interval there is no reflected wave, or $2f(T) = 0$, and Equation (16b) represents a straight line through A_0 with a tangent $-\frac{V_w}{g}$ as represented at $A_0 P$ in Fig. 7(*a*). For a closing motion of the gate, reducing the velocity to V_1 in $T \leqq \frac{2L}{V_w}$, the rise in pressure is given by Line $C D$ which corresponds to $-\frac{V_w}{g}(V_0 - V_1) = H_1 - H_0$, as shown in Fig. 7(*a*), and Equation (16*a*) shows that the direct wave, $C D$, equals $F_1(T)$ (see also Equation (7)), since,

$$2 F_1(T) = H_1 - H_0 + \frac{V_w}{g}(V_0 - V_1) \qquad \text{(17)}$$

When the opening occurs from a closed gate, $V_0 = 0$, at $H = H_0$, and the line, $A_0 C$, is the locus of the values of H as before. Both $V_0 - V_1$ and $H_1 - H_0$ are negative in this case (see Fig. 7(*b*)). If, however, the velocity, $V = V_2$, is not reached until an interval beyond the first—for example, in the time $2\left(\frac{2L}{V_w}\right) > T > \frac{2L}{V_w}$—then the pressure reached is modified by the reflected wave. When the gate is being closed, the previous discussion shows that the reflected wave produces a negative pressure equal in magnitude, but opposite in sign, to the direct or F-wave produced in the previous interval. In Fig. 7(*c*) let V_1 be the velocity reached at the end of the first interval, then the pressure corresponding to this velocity will be represented at Point A_1 and Line $A_1 E$ is the pressure rise, or the value of $F_1(T)$ in the first phase. It is also the numerical value of the reflected pressure or f-wave in the second interval; that is,

$$\overline{A_1 E} = -f_2(T) \qquad \text{(18)}$$

Equation (16*b*) with Fig. 7(*c*) shows that,

$$A_2' F = +\frac{V_w}{g}(V_0 - V_2) \qquad \text{(19a)}$$

and,

$$2 A_1 E = A_1 K = -2 F_1(T) = 2 f_2(T) \qquad \text{(19b)}$$

Hence, $H_2 - H_0 = A_2 F$; and, A_2 represents the conditions corresponding to the change of velocity, $V_0 - V_2$, since $A_2' A_2 = A' K$. Point A_2 is determined graphically either by making Line $E K$ = Line $A_1 E$ and drawing Line $K A_2$ parallel to Line $A_0 P$; or, by drawing Line $A_1 G$ at the slope $+\frac{V_w}{g}$ (that is, $\overline{A_0 E} = \overline{E G}$) and drawing Line $G A_2$ parallel to Line $A_0 P$.

When the gate is being opened, the result is quite similar. Suppose the gate is opened from a closed position with $V_0 = 0$ and the velocity, V_1, is reached in the first interval, it is evident that Line $C D$, Fig. 7(*b*), represents $H_0 - H_1$. If the velocity, V_2, is reached in the second interval, the construction would be as shown in Fig. 7(*d*), in which both $V_0 - V_2$ and $H_2 - H_0$ are negative, the slope of the line has the same tangent, $-\frac{V_w}{g}$, as before, and

A_1 represents the pressure at the end of the first interval. Therefore, $F_1\,(T)$ is negative and $f_2\,(T)$ is positive and equal to $A_1\,E$, and the point, A_2, representing H_2 lies at A_2 above A_2'. Equations (16), therefore, are easily represented by this graphical construction.

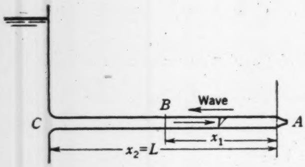

FIG. 8

These two formulas, Equations (15), then, define the laws of the graphical method, and it only remains to re-arrange them into a more useful form. Applying them to the pipe shown in Fig. 8 (in which case T_0, T_1, and T_2, denote the times that the same direct wave passes, respectively, Point A on the pipe at the origin, Point B at a distance, x, and Point C at the reservoir, which is a distance, $x_2 = L$ from Point A), it is to be noted that,

$$T_1 = T_0 + \frac{x_1}{V_w} \ldots\ldots\ldots\ldots\ldots\ldots (20a)$$

and,

$$T_2 = T_0 + \frac{x_2}{V_w} \ldots\ldots\ldots\ldots\ldots\ldots (20b)$$

Therefore, while the direct wave is proceeding from Point A on the pipe to Point C, the following equations apply (using H_{A0}, etc., to denote the steady condition):

$$H_{AT0} - H_{A0} = -\frac{V_w}{g}(V_{A0} - V_{AT0}) + 2\,F\,(T_0) \ldots\ldots\ldots (21a)$$

$$H_{BT1} - H_{B0} = -\frac{V_w}{g}(V_{B0} - V_{BT1}) + 2\,F\left(T_1 - \frac{x_1}{V_w}\right)$$

$$= -\frac{V_w}{g}(V_{B0} - V_{BT1}) + 2\,F\,(T_0) \ldots\ldots\ldots\ldots (21b)$$

and,

$$H_{CT2} - H_{C0} = -\frac{V_w}{g}(V_{C0} - V_{CT2}) + 2\,F\left(T_2 - \frac{x_2}{V_w}\right)$$

$$= -\frac{V_w}{g}(V_{C0} - V_{CT2}) + 2\,F\,(T_0) \ldots\ldots\ldots\ldots (21c)$$

Furthermore, while the reflected wave is proceeding toward the gate, the reverse of Fig. 8, and reaches Point B at the time, T_3, and Point A at the time, T_4, the following equations apply:

$$H_{CT2} - H_{C0} = +\frac{V_w}{g}(V_{C0} - V_{CT2}) + 2\,f\left(T_2 + \frac{x_2}{V_w}\right)$$

$$= +\frac{V_w}{g}(V_{C0} - V_{CT2}) + 2\,f\,(T_4) \ldots\ldots\ldots\ldots (22a)$$

$$H_{BT3} - H_{B0} = +\frac{V_w}{g}(V_{B0} - V_{BT3}) + 2\,f\left(T_3 + \frac{x_1}{V_w}\right)$$

$$= +\frac{V_w}{g}(V_{B0} - V_{BT3}) + 2\,f\,(T_4) \ldots\ldots\ldots\ldots (22b)$$

and,

$$H_{AT_4} - H_{A0} = +\frac{V_w}{g}(V_{A0} - V_{AT_4}) + 2f(T_4) \ldots\ldots\ldots (22c)$$

Generally, at any point, such as Point B, and at any instant, two waves are proceeding: The direct wave toward Point C; and the reflected wave toward Point A. For the direct wave the pressure rise above the initial steady pressure, H_{B0}, at Point B is given by Equation (21*b*), and for the reflected wave it is given by Equation (22*b*). If friction is not being considered, then $H_{A0} = H_{B0} = H_{C0}$ as the water level will be the same in piezometers attached to the pipe at Points A, B, and C; and subtractions of Equations (21) and (22), made in suitable order, give:

$$H_{AT_0} - H_{BT_1} = +\frac{V_w}{g}(V_{AT_0} - V_{BT_1}) \ldots\ldots\ldots\ldots (23a)$$

$$H_{BT_1} - H_{CT_2} = +\frac{V_w}{g}(V_{BT_1} - V_{CT_2}) \ldots\ldots\ldots\ldots (23b)$$

$$H_{CT_2} - H_{BT_3} = -\frac{V_w}{g}(V_{CT_2} - V_{BT_3}) \ldots\ldots\ldots\ldots (23c)$$

and,

$$H_{BT_3} - H_{AT_4} = -\frac{V_w}{g}(V_{BT_3} - V_{AT_4}) \ldots\ldots\ldots\ldots (23d)$$

The case illustrated is that of a pipe discharging from a reservoir through a closing gate. A very common case is also that of a pump discharging through a pipe into a reservoir, as shown in Fig. 6(*c*). The flow is controlled by a gate near the pump, the movement of the gate causing pressure disturbances. It has already been shown that the algebraic signs of the fundamental differential equations are the opposite of those in the case of Fig. 8. This only means that all terms on the right-hand side containing V will change sign, and, hence, for the case of the pump with controlling discharge valve near it, the Equations (23) would be written:

$$H_{AT_0} - H_{BT_1} = -\frac{V_w}{g}(V_{AT_0} - V_{BT_1}) \ldots\ldots\ldots\ldots (24a)$$

and,

$$H_{BT_1} - H_{CT_2} = -\frac{V_w}{g}(V_{BT_1} - V_{CT_2}) \ldots\ldots\ldots\ldots (24b)$$

etc., the letters, A and C, referring to the valve and reservoir ends, respectively, of the pipe, as in the previous case. In Fig. 8, let $x_2 = 10\,000$ ft, in which the length, $x_1 = 4\,500$ ft, and $V_w = 4\,000$ ft per sec. Then, reckoning time from the beginning of closure, it follows that $T_0 = 0$; $T_1 = 0 + \frac{4\,500}{4\,000} = 1.125$ sec; $T_2 = 0 + \frac{10\,000}{4\,000} = 2.5$ sec; $T_3 - T_2 = \frac{10\,000 - 4\,500}{4\,000} = 1.375$ sec; and, $T_4 - T_3 = \frac{5\,000}{4\,000} = 1.125$ sec.

For many problems the series of equations is best left in the form shown in Equations (23) or Equations (24), and some illustrations will be given subsequently in which this method is adopted; but it often happens that the engineer is more interested in the proportional rise in pressure than in the actual pressure and wishes to know the ratio, $\frac{H}{H_0}$, directly. The results are the same whether one obtains H, $H - H_0$, or $\frac{H}{H_0}$; it is purely a matter of convenience for the particular application. If the equations are modified to yield the value of $\frac{H}{H_0}$, Equation (23*a*) may be written:

$$\frac{H_{AT0}}{H_0} - \frac{H_{BT1}}{H_0} = 2\,\frac{V_w\,V_{A0}}{2\,g\,H_0}\left(\frac{V_{AT0}}{V_{A0}} - \frac{V_{BT1}}{V_{A0}}\right) \qquad (25)$$

Ordinarily, small letters are used to designate the ratios; thus: $h_{BT1} = \frac{H_{BT1}}{H_0}$; $v_{BT1} = \frac{V_{BT1}}{V_{B0}}$, etc. Furthermore, the relation, $\frac{V_w\,V_{A0}}{2\,g\,H_0} = \rho$, will be referred to as the pipe-line characteristic, as defined by Allievi. Similar relationships are found for the other equations and Equations (23) then take the form:

$$h_{AT0} - h_{BT1} = +\,2\,\rho\,(v_{AT0} - v_{BT1}) \qquad (26a)$$

$$h_{BT1} - h_{CT2} = +\,2\,\rho\,(v_{BT1} - v_{CT2}) \qquad (26b)$$

$$h_{CT2} - h_{BT3} = -\,2\,\rho\,(v_{CT2} - v_{BT3}) \qquad (26c)$$

and,

$$h_{BT3} - h_{AT4} = -\,2\,\rho\,(v_{BT3} - v_{AT4}) \qquad (26d)$$

which is the form in which they are mostly commonly used in the graphical construction. For the pumping system (see Equations (10)), the algebraic signs of the second terms would be reversed.

The derivation of Equations (23), (24), and (26) has been made for closing movements of the gate only, but they will apply in exactly the same form to opening movements, because in this case, the change of pressure has the opposite sign to the change of velocity as in the case of closure; therefore, the two series (Equations (23) and (26) and the corresponding formulas for the pumping system) apply also to opening movements.

To represent Equations (26) graphically, axes of h and v, Fig. 9, are assumed, the origin having the value, $h = 0$, $v = 0$. The values of h should preferably be plotted on the vertical axis. Continuing still with the problem of closure, as in Fig. 6(*a*), the values at Point A during steady flow before closure begins are $H = H_0$ and $V = V_0$; hence, at the start, $h = 1$ and $v = 1$, corresponding to the time, T_0, in Equations (26). Furthermore, the pressure wave does not reach Point B until the time, T_1, and does not reach Point C until the time, T_2, therefore, up to these respective times the conditions at Points B and C remain unchanged, or $h_{BT1} = h_{CT2} = 1$, and $v_{BT1} = v_{CT2} = 1$. In Fig. 9(*a*), a point A_{T0}, will represent the conditions at Point A at the time,

T_0; similarly, B_{T1} will represent those at Point B at the time, T_1, etc. Therefore, A_{T0}, B_{T1}, and C_{T2} are all at Point $h = 1$, $v = 1$.

For this problem, if it is assumed that the reservoir level is constant, then all values of $h_C = 1$, and hence all points, C, must lie at $h = 1$ on the axis

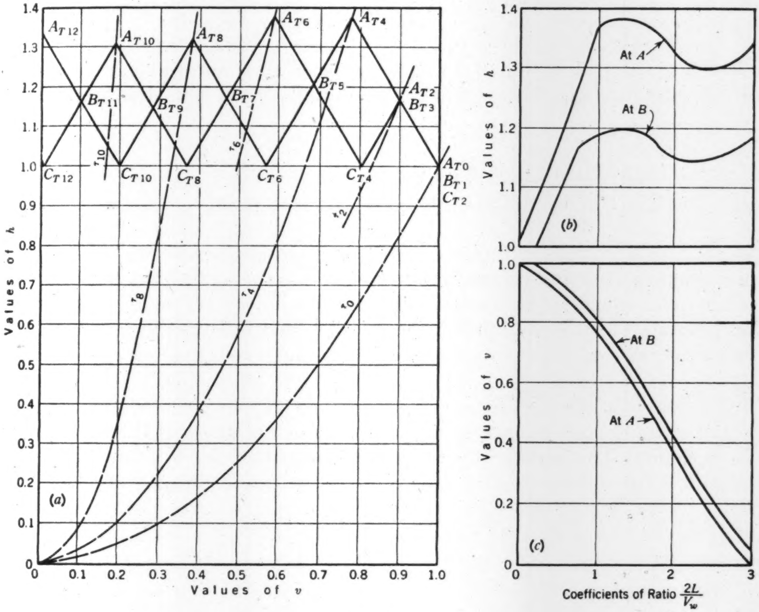

FIG. 9

of v; Equations (26a) and (26b) are then represented by a point. It may be simplest for the moment to proceed at once from Points A to C, thus combining Equations (26c) and (26d) into:

$$h_{CT2} - h_{AT4} = -2\rho\,(v_{CT2} - v_{AT4}) \ldots\ldots\ldots\ldots\ldots (27)$$

This is evidently a line through C_{T2} sloping at the angle, $\tan^{-1} - 2\rho$, which defines one line on which A_{T4} lies. It is now necessary to establish the law connecting the head, H_A, and the velocity, V_A, at the gate. No matter what form the gate has, the velocity of discharge from it is,

$$V_A = c_d\sqrt{2\,g\,H_A} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (28)$$

in which c_d is the coefficient of discharge, and in which the discharge is found by multiplying this velocity by A_g, the area of the gate-opening. Hence, the pipe velocity is,

$$V_A = \frac{A_g \times c_d\sqrt{2\,g\,H_A}}{A_a} = B\sqrt{H_A} \ldots\ldots\ldots\ldots\ldots (29)$$

in which B is a function of the effective gate area, $(c_d A_g)$; and, therefore, B is a function of the time. For the initial steady condition:

$$V_{A0} = B_0 \sqrt{H_0} \qquad (30a)$$

and, therefore:

$$\frac{V_A}{V_{A0}} = \frac{B}{B_0} \sqrt{\frac{H_A}{H_0}} = \tau \sqrt{\frac{H_A}{H_0}} \qquad (30b)$$

in which τ is also a function of the time and has a maximum value, $\tau = \tau_0 = 1$, for full gate-opening. Expressing Equation (30b) in the notation adopted:

$$v_A = \tau \sqrt{h_A} \qquad (31a)$$

or, at the time, T_4, at Point A on the pipe:

$$v_{AT4} = \tau_4 \sqrt{h_{AT4}} \qquad (31b)$$

Equation (31b) is evidently the formula for a parabola with its vertical axis coinciding with that of h and with its vertex at $h = 0, v = 0$. Since $\tau = \tau_0 = 1$ for the full open gate, the corresponding curve will pass through $h = 1, v = 1$, and is easily plotted. Similarly, the parabola for τ_4 is readily drawn if the law of gate closure is known, because for each instant during gate motion the value of $\frac{B}{B_0} = \tau$ is known.

If a parabola corresponding to τ_4 is drawn in Fig. 9(a), it will be the locus of the points, A_{T4}, and where it intersects the other line containing A_{T4}, it will locate the desired point. It is now possible to locate B_{T3} and, for simplicity, B will be assumed at the center of the pipe. Equations (26) show that it lies on the line, $C_{T2} - A_{T4}$, and following the method already adopted, one may write:

$$h_{AT2} - h_{BT3} = + 2 \rho (v_{AT2} - v_{BT3}) \qquad (32)$$

but A_{T2} lies on the parabola, with the value, τ_2, found as in the case of that for A_{T4} (for linear closure, $\tau_2 = \frac{1}{2}(1 + \tau_4)$), and, therefore, Equation (32) represents a point and B_{T3} coincides with A_{T2}. If one desired to know the conditions at Point A one interval later, it would be necessary to find the point, A_{T8}, for which the following equations would be written:

$$h_{AT4} - h_{CT6} = 2 \rho (v_{AT4} - v_{CT6}) \qquad (33a)$$

and,

$$h_{CT6} - h_{AT8} = - 2 \rho (v_{CT6} - v_{AT8}) \qquad (33b)$$

Passing through A_{T4}, Equation (33a) locates C_{T6} (for which $h = 1$), and Equation (33b), passing through C_{T6}, gives A_{T8} on the parabola, τ_8, drawn similarly to τ_4. Fig. 9(a) has been drawn for $\rho = 0.8$ and for closure in three intervals, conditions at Point A and Point B being shown. The corresponding values of v and h have been plotted on a time base in Fig. 9(b) and Fig. 9(c). Evidently, in solving such a problem it is necessary to know: (a) Complete data on the conditions in the pipe for initial steady flow; (b) the law of variation of gate-opening with time; and (c) further information about the conditions at some other point such as C. When the pipe is connected to a large open reservoir, or to a large surge tank, the variations of water level in the latter during the water-hammer period are generally negligible, because the water-hammer intervals are very short compared with those required for the mass movement of the water. Practically, however, there is no difficulty in dealing with variations of level at Point C, or with any other condition that may exist there. With water-turbine gates the linear law of movement is used approximately, but for ordinary hand-controlled gates the movement may be quite irregular; once the effective areas are known, however, on a time base, the values of τ for each interval or fraction thereof are known and the problem is easily solved. Of course, the spacing of the τ-lines will not be uniform in the latter case.

GATE-OPENING

For gate-openings, precisely the same set of equations is used, but the value of V to be chosen in computing ρ requires some thought. If the gate is opened from a closed position, the initial pipe velocity is zero and, of course, cannot be used; and if it is moved from one open position to another position with larger area, there are two steady velocities, that at the beginning and that at the end of the movement. An examination of the theory will show that either of these velocities may be used, and v will then be solved for relative to the selected reference velocity. It is always most convenient to use the steady velocity corresponding to the final position of the gate within the limits of the problem, because this gives values of v less than unity on the whole, and such values are easier to work with than when all values of v exceed unity. For that reason this method has been adopted herein, although the same results will be obtained for the other values of V, provided the meanings of ρ and v are kept in mind.

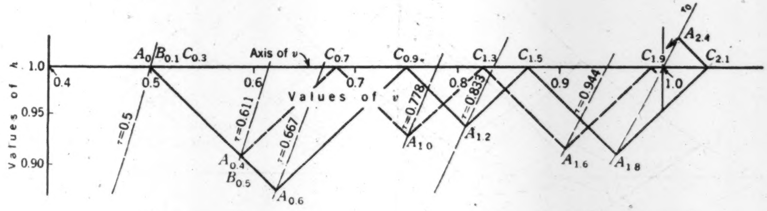

FIG. 10.—OPENING FROM HALF TO FULL GATE IN $T = 3\left(\frac{2L}{V_w}\right) = 18$ SEC

The example shown in Fig. 10 is for a pipe working under a head, $H_0 = 800$ ft, and with a steady velocity, $V_1 = 4$ ft per sec; and the changes of pressure have been determined at Point A and also at Point B ($x_1 = \frac{1}{3}L$). The valve is opened in 1.8 sec to such a position that the final steady velocity will be $V_2 = 8$ ft per sec; and, $V_w = 3\,500$ ft per sec has been assumed. If the pipe is 1 050 ft long, then $\frac{2L}{V_w} = 0.6$ sec; and, hence, $T = 1.8$ sec $= 3\left(\frac{2L}{V_w}\right)$ sec. In other words, opening occupies three intervals. Furthermore, $\rho = \frac{3\,500 \times 8}{2 \times 32.2 \times 800} = 0.543$, so that the lines in Fig. 10 have a slope such that $\tan^{-1} \pm 2 \times 0.543 = \tan^{-1} \pm 1.086$. The equations for the solution of this problem are written from Equations (26). The parabolas, $\tau = 0.5$, $\tau_1 = 0.667$, $\tau_2 = 0.833$, and $\tau_3 = \tau_0 = 1$, are drawn in light lines, but since Point B is at $x_1 = \frac{1}{3} L$, the parabolas one-third the way between the foregoing are also drawn dotted; for example: $\tau = 0.611$, $\tau = 0.778$, and $\tau = 0.944$. The starting point is evidently at Point A_0, Fig. 10, where $v_{A0} = 0.5$; and $h_{A0} = 1$. This point is also $B_{0.1}$ and $C_{0.3}$, and the construction should be followed without difficulty. (In all values such as $B_{0.1}$, etc., the subscript following each letter gives the time, in seconds, at which the values of h and v are represented by the point.) The actual head at the point at the time marked, of course, will be the indicated value of h multiplied by $H_0 = 800$ ft, and the actual velocity is the value of v multiplied by the reference velocity, $V_2 = 8$ ft per sec. All points, $A_{1.8}$ and beyond, are plotted on $\tau_0 = 1$. Since the gate remains in a fixed position from that time on, the pressures along the pipe reach H_0 quickly.

COMPOUND PIPES

The analytical solution for the pressures in compound and branched pipes becomes extremely difficult, if not actually impossible, in many cases; and yet the graphical construction furnishes a very simple method of solving the same problems. The first illustration is the pipe of Fig. 11, consisting of three parts of different lengths and diameters, all necessary data being shown on the inset. In order to clarify the illustration, linear gate closure and convenient ratios between the values of $\frac{L}{V_w}$ have been assumed. Any other data

may be treated just as easily although the drawing might have more lines on it and, therefore, might become larger. Only the first few equations will be written:

$$h_{A0} - h_{B3} = +\,2\,\rho_a\,(v_{A0} - v_{B3}) \quad \text{(34a)}$$

$$h_{B3} - h_{C5} = +\,2\,\rho_b\,(v_{B3} - v_{C5}) \quad \text{(34b)}$$

$$h_{C5} - h_{D6} = +\,2\,\rho_c\,(v_{C5} - v_{D6}) \quad \text{(34c)}$$

$$h_{B3} - h_{A6} = -\,2\,\rho_a\,(v_{B3} - v_{A6}) \quad \text{(34d)}$$

$$h_{A4} - h_{B7} = +\,2\,\rho_a\,(v_{A4} - v_{B7}) \quad \text{(34e)}$$

$$h_{C5} - h_{B7} = -\,2\,\rho_b\,(v_{C5} - v_{B7}) \quad \text{(34f)}$$

$$h_{A2} - h_{B5} = +\,2\,\rho_a\,(v_{A2} - v_{B5}) \quad \text{(34g)}$$

$$h_{B5} - h_{C7} = +\,2\,\rho_b\,(v_{B5} - v_{C7}) \quad \text{(34h)}$$

and,

$$h_{D6} - h_{C7} = -\,2\,\rho_c\,(v_{D6} - v_{C7}) \quad \text{(34i)}$$

Equations (34*a*), (34*b*), and (34*c*) correspond to the single points, A_0, B_3 C_5, D_6, at $h = 1$, $v = 1$; Equation (34*d*) locates the line, $B_3\,A_6$, on $A_0\,A_6$, since A_6 is fixed by the value corresponding to the time and consequent gate-opening at the end of one interval for Section $A\ B$, Fig. 11. Having determined the values of A_0 and A_6, the points, A_2 and A_4, are found by the method described for the simple pipe. Equation (34*e*) with Equation (34*f*) locates Point B_7 and Equation (34*g*) then gives Point B_5; from these, Equations (34*h*) and (34*i*) serve to locate Point C_7. By writing out the successive equations, the points, D_8, C_9, D_{10}, B_9, C_{11}, etc., may be found. All A–B lines have the slope, $\pm\,2\,\rho_a$, all B–C lines, the slope, $\pm\,2\,\rho_b$, and all C–D lines, the slope, $\pm\,2\,\rho_c$. All points, D, are on the line, $h = 1$, since the reservoir level is assumed constant.

Whereas the pressures at Point A rise continually until closure and then fall rapidly, the pressures at Point B rise quickly during the first 9 sec; then they remain nearly constant to the 15th sec, after which they fall. On the other hand, the pressures at Point C remain nearly constant for the first 17 sec, after which they become less than H_0. The velocities may also be read easily, but usually are not desired. A pipe with any number of sections may be investigated just as easily, although those with fractional values of $\frac{L}{V_w}$ may require a lengthy but simple construction, similar to Fig. 11. It is to be noted further that all the values of ρ are connected since they are all referred to the same values of H_0 and, therefore, must be related in the same manner as the pipe areas.

BRANCHED PIPES; THE SURGE TANK

Pipes with branches form a particularly useful application of the principles under discussion, and these include penstocks with surge tanks, water pipes with a branch parallel to parts of the main line, but connected to the line at both ends of the branch, branches with dead ends, etc. Perhaps the easiest case to begin with is the water-power system with an open-top surge tank (*b*) between the conduit (*c*) and the penstock (*a*), as illustrated in Fig. 12, in which Point A

is the gate (it would be a turbine in this case), Point B, the junction point of the penstock, conduit, and tank, Point D, the water surface in the tank, and Point C is at the conduit entrance. The case of load rejection with non-linear gate closure will be considered.

FIG. 12.—NON-LINEAR GATE CLOSURE IN $T = 2\left(\frac{2L}{V_w}\right) = 8$ SEC

When the load is rejected, a mass movement of the water takes place up into the tank; but compared to the interval, $2\frac{L}{V_w}$, for the penstock or tank, this movement is quite slow, and with tanks of usual proportions the change of level of the tank, say, for five intervals of $\frac{2L}{V_w}$ sec of either the tank or the penstock would be negligible as far as it affected the pressure at Point B. On the other hand, the gate movement produces pressure or water-hammer waves, which are very rapid and which, at times, do produce serious pressure changes at Point B; but in the first instance, at least, changes of level at Point C and Point D are not considered. It then follows that in the graphical representation all Points C and D lie on the line, $h = 1$.

The method of dealing with this case is the same as the others. Friction and velocity head being neglected, the pressure at a given instant at Point B is the same whether it is considered as a point in (a), (b), or in (c). Hence,

$$h_{aB} = h_{bB} = h_{cB} = h_B \dots\dots\dots\dots\dots\dots (35)$$

and during steady flow, $h_{B0} = 1$. In addition, if the positive direction of V_c is toward Point B, while those of V_a and V_b are away from Point B, the equation of continuity for that point will be written, $Q_c = Q_a + Q_b$; or, $Q_a = Q_c - Q_b$; that is,

$$A_a\,V_a = A_c\,V_c - A_b\,V_b \dots\dots\dots\dots\dots\dots (36a)$$

For steady flow Equation (36a) becomes,

$$A_a\,V_{a0} = A_c\,V_{c0} - A_b\,V_{b0} \dots\dots\dots\dots\dots\dots (36b)$$

Dividing Equation (36a) by $A_a\,V_{a0}$ gives $\frac{A_a\,V_a}{A_a\,V_{a0}} = \frac{A_c\,V_c}{A_a\,V_{a0}} - \frac{A_b\,V_b}{A_a\,V_{a0}}$; or,

$$\frac{A_a\,V_a}{A_a\,V_{a0}} = \frac{A_c\,V_{c0}\,V_c}{A_a\,V_{a0}\,V_{c0}} - \frac{A_b}{A_a}\frac{V_{b0}}{V_{a0}}\frac{V_b}{V_{b0}} \dots\dots\dots\dots (37)$$

In the notation already adopted the left-hand term is written v_a and each of the two right-hand terms has the same form as the left-hand one, thus, the term, $\frac{A_c\,V_{c0}\,V_c}{A_a\,V_{a0}\,V_{c0}}$, contains a fixed constant multiplied by the velocity ratio, $\frac{V_c}{V_{c0}}$, and the entire term may be written, v_c, by arbitrarily defining V_{c0} so that $A_c\,V_{c0} = A_a\,V_{a0}$. A similar statement applies to the second right-hand term, and, therefore, Equation (37) may be written,

$$v_a = v_c - v_b \dots\dots\dots\dots\dots\dots\dots\dots (38)$$

This method of defining V_{c0} and V_{b0} at once gives a value to the velocities used in finding ρ for the pipes, (a), (b), and (c), and, therefore, these values of ρ will be written:

$$\rho_a = \frac{V_{wa}\,V_{a0}}{2\,g\,H_0} \dots\dots\dots\dots\dots\dots\dots\dots (39a)$$

$$\rho_b = \frac{V_{wb}\,V_{b0}}{2\,g\,H_0} = \frac{A_a}{A_b}\,\rho_a\,\frac{V_{wb}}{V_{wa}} \dots\dots\dots\dots (39b)$$

and,

$$\rho_c = \frac{V_{wc}\,V_{c0}}{2\,g\,H_0} = \frac{A_a}{A_c}\,\rho_a\,\frac{V_{wc}}{V_{wa}} \dots\dots\dots\dots (39c)$$

Using Equations (38) and (39) this problem presents no more difficulty than the simple pipe. It is possible to follow the methods described at the beginning of this paper and represent the conditions in the three pipes, (*a*), (*b*), and (*c*), Fig. 12, on a single diagram, but the latter then becomes very complicated and it will be better to draw them separately. The data for the problem are given in Fig. 12, the tank area being assumed uniform and equal to four times the penstock area and the head, $H_0 = 300$ ft. The data assumed give $\rho_a = 1.00$, $\rho_b = 0.25$, and $\rho_c = 0.667$, and closure is assumed in two intervals of the conduit; that is, 8 sec. The lengths of the pipe and tank have been distorted deliberately so that the problem may be solved on a small sheet and still show the principles. In attacking these problems it is best and quickest to have the three diagrams side by side so that all axes of v are in the same straight line; to save space, the figures have been moved from their original positions used when solving the problem.

The diagram for A_2 and A_4 for the penstock, (*a*), should require no explanation, the points, $A_0\,B_2$, $B_2\,C_6$, $B_2\,D_3$, evidently are placed correctly at each starting point and, although v_a and v_c are measured to the right, it is necessary to measure v_b to the left, as it has a negative sign. Having found A_2 and A_4, the formula, $h_{A2} - h_{B4} = +\,2\,\rho_a\,(v_{A2} - v_{B4})$ (from Equations (26)), gives one line on which B_4 lies. The point, B_4, however, must be at the same height in the diagrams for Pipes (*a*), (*b*), and (*c*) from Equation (35) and also, from Equation (38),

$$v_{aB4} = v_{cB4} - v_{bB4} \dots\dots\dots\dots\dots\dots\dots (40)$$

The notation in Equation (40) is complicated but v_{aB4} is written for the velocity in Pipe (*a*) at the point, B, and 4 sec after gate motion begins. Equation (40) shows that Point B_4 lies on a line, $A_0\,M$, located as follows: $v_a = 0$ in Equation (40) if $v_b = v_c$, all being taken at the same pressure. This is easily seen to be the pressure at which a line (not shown for lack of space) through the point, $v_c = 0$, $h = 1$ at slope $+\,2\,\rho_b$ on the (*c*)-diagram, intersects a line through the point, $v_c = 1$, $h = 1$, and at the slope, $-\,2\,\rho_c$ on the same diagram. This point, so found on Conduit (*c*), gives the height of the Point M so that M represents the same pressure; B_4 then lies on $A_0\,M$. This also locates B_4 on the (*b*) and (*c*)-diagrams since,

$$h_{D3} - h_{B4} = -\,2\,\rho_b\,(v_{D3} - v_{B4}) \dots\dots\dots\dots (41a)$$

and,

$$h_{C6} - h_{B10} = -\,2\,\rho_c\,(v_{C6} - v_{B10}) \dots\dots\dots\dots (41b)$$

and B_4 clearly lies on $B_2 - B_{10}$, or this line produced.

Next, A_6 is found since it lies on $B_4\,A_6$ from the equation,

$$h_{B4} - h_{A6} = -\,2\,\rho_a\,(v_{B4} - v_{A6}) \dots\dots\dots\dots (42)$$

It also lies on the parabola corresponding to 6 sec after closure begins. The next point is D_5 which lies on Line $B_4\,D_5$ at Slope $+\,2\,\rho_b$ and at $h = 1$. Next, B_6 lies on a line through D_5 since,

$$h_{D5} - h_{B6} = -\,2\,\rho_c\,(v_{D5} - v_{B6}) \dots\dots\dots\dots (43)$$

and it also lies on $A_4 B_6$ of the slope, $+ 2 \rho_a$ and, furthermore, it must be located so that $v_{aB6} = v_{cB6} - v_{bB6}$. A little consideration will show that it must then lie on a line parallel to $A_0 M$, but horizontally displaced to the left by a distance, $D_5 D_3$.

The remainder of the construction is similar. To locate such a point as B_{14}, the line, $A_0 M$, is displaced horizontally by the distance, $(D_3 - D_{13}) + (C_6 - C_{10})$, and, similarly, for other points.

It is well to check the method frequently by scaling the drawings and remembering that the continuity equation holds at Point B at any instant and pressure. Thus, the point, B_8, represents the conditions at Point B at 8 sec after closure begins, and scaling from the drawing at this point for each section gives $v_a = -0.05$; $v_b = 0.97$; and $v_c = 0.92$, so that $v_a = v_c - v_b = 0.92 - 0.97 = -0.05$, as it should. At this instant, all the water flowing through the conduit, (*c*) Fig. 12, together with some water from the penstock, (*a*), is flowing into the tank. However, at 10 sec after closure begins the water is coming from the penstock at a high rate, as shown at B_{10} on the diagram for Penstock (*a*). It must not be thought, however, that water is actually flowing into the nozzle from without, for no Point A ever gets to the left of the axis of h, although all points, from A_8 on, lie on this line because the gate is closed.

A little care is needed in the interpretation of the results; for example, at 6 sec, the point, B_6, corresponds to $h = 1.13$ and, therefore, to a rise in pressure at Point B of $0.13 \times H_0 = 39$ ft, and, similarly, for other points.

Although the left-hand scale for Tank (*b*), Fig. 12, is confusing at first, it soon ceases giving any trouble. In dealing with all such problems the points, A, must be chosen close enough together to enable the solution to be made. In most cases the ratio of $\frac{2L}{V_w}$ has the smallest value for the tank, but whether it has or has not, the time unit is selected at least as small as the lowest value of $\frac{2L}{V_w}$ in the system and parabolas are drawn with this time spacing. In this case, the smallest value of this term is 2 sec in the tank and on Fig. 12, therefore, values of A are found for each 2 sec. When the periods of the pipes are not multiples of one another, a sufficient number of values of A must be found to complete the problem, and sometimes the work is prolonged, but gives no trouble of any kind.

The volume of water flowing into the tank due to water hammer is easily computed. At 4 sec, $v_{bB} = 0.14$, and the volume passing into the tank in the first 4 sec, therefore, is:

$$A_a V_{bB} \times \frac{2 L_b}{V_{wb}} = v_{bB} v_{a0} A_a \frac{2 L_b}{V_{wb}} = 0.14 Q_0 \frac{2 L_b}{V_{wb}} \quad \ldots\ldots\ldots (44)$$

in which by definition of V_{b0}, $Q_0 = A_a V_{a0} = A_b B_{b0}$ is the initial steady flow. At the end of 6 sec, the total volume that has passed in is $(v_{bB4} + v_{bB6}) Q_0 \times \frac{2 L_b}{V_{wb}}$ cu ft. The velocities, of course, are all measured on the diagram for Tank (*b*) and, for accuracy, D_5 and D_7 should be raised above $h = 1$ to suit this increased volume; but usually the change of level is so small as to have no practical effect.

WATER MAIN WITH BRANCH; EFFECT OF DEAD END

The next example is the case of the water pipe illustrated in Fig. 13 and Fig. 14. It represents a 15-in. pipe supplied by a reservoir with constant level and discharging through a nozzle or gate, for which it is assumed the law of closure is known. This pipe has an 18-in. branch connected to the main at Points B and C in Fig. 13, but only at Point B in Fig. 14, the free end of the 18-in. pipe being plugged in this latter case. The pressures in the pipe are sought in the two cases, and, in that way, a comparison is possible between the closed circuit and the one with "dead end" under exactly similar conditions.

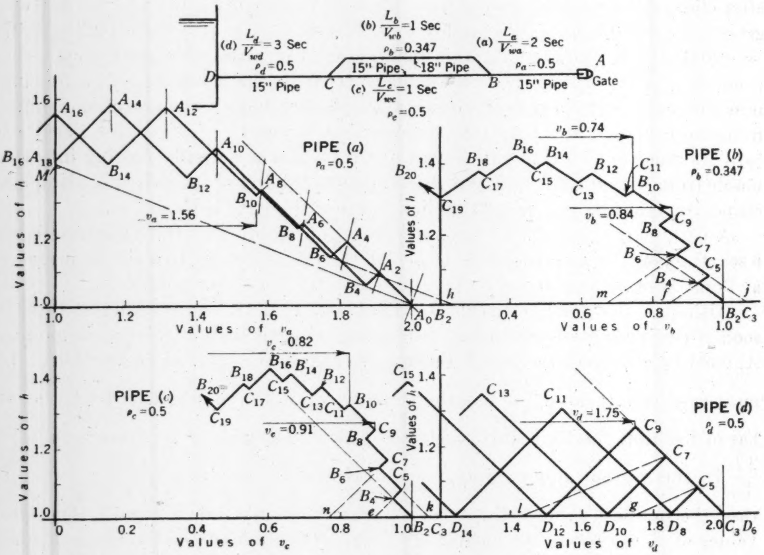

FIG. 13.—LINEAR GATE CLOSURE IN 4 $\left(\frac{L_a}{V_{wa}}\right)$ = 16 SEC; 18-INCH BRANCH CONNECTED TO MAIN AT TWO POINTS

Starting with the first case (Fig. 13), separate diagrams will be made for the four parts, (*a*), (*b*), (*c*), and (*d*), designated in the drawing. The data are selected to give values of $\frac{L}{V_w}$ in the four parts as 2 sec, 1 sec, 1 sec, and 3 sec, respectively, and, also, $\rho_a = 0.5$, from which the previous discussion shows that this is also the value of ρ_c and ρ_d, and that $\rho_b = \frac{A_c}{A_b}\rho_a = 0.347$.

Furthermore, assuming that all velocities have their positive directions toward Point A, the continuity equation at Point B is $v_a = v_b + v_c$, and at Point C, it is $v_d = v_b + v_c$. Therefore, the point, A_0, in Fig. 13(*a*), corresponds to $v_{a0} = 2$; in Fig. 13(*b*) and Fig. 13(*c*) both v_{b0} and v_{c0} are unity, whereas, in Fig. 13(*d*), the value is $v_{d0} = 2$. The initial starting points on the four diagrams are designated $A_0 B_2$, $B_2 C_3$, $B_2 C_3$, and $C_3 D_6$, in accordance with the notation already adopted, and the slopes of the principal lines on these diagrams are $\pm 2 \rho_a$ etc.; furthermore, in Fig. 13(a), parabolas for 2 sec, 4 sec, 6 sec, etc., after closure begins, are drawn and the points, A_2 and A_4, are found in the usual manner. Point B_4 is located at the same elevation in Fig. 13(a), Fig. 13(b), and Fig. 13(c), and also, for this point, $v_a = v_b + v_c$; and in order to carry out this condition, an auxiliary line, $A_0 M$, is drawn, exactly as in Fig. 12, such that at any pressure the velocity shown by $A_0 M$ is the sum of the velocities in Fig. 13(b) and Fig. 13(c) at the same pressure. Then,

$$h_{A2} - h_{B4} = + 2 \rho_a (v_{A2} - v_{B4}) \dots\dots\dots\dots\dots (45)$$

gives the line, A_2-B_4, and, consequently, the point, B_4, and this point is then projected over to Fig. 13(b) and Fig. 13(c).

Next Point C_5 is to be found and the equations by which it is located are, for Fig. 13(b):

$$h_{B4} - h_{C5} = + 2 \rho_b (v_{B4} - v_{C5}) \dots\dots\dots\dots\dots (46a)$$

and for Fig. 13(c):

$$h_{B4} - h_{C5} = + 2 \rho_c (v_{B4} - c_{C5}) \dots\dots\dots\dots\dots (46b)$$

so that lines through Point B_4 representing these equations are drawn on the two diagrams. The continuity equation also gives $v_b + v_c = v_d$ so that Point C_5 will also lie on a line, $g C_5$ (Pipe d), having the same inclination as $A_0 M$, but with its tangent of opposite sign, the point, g, being located so that $B_2 e + B_2 f = D_6 g$. (This is quite easy to demonstrate by geometry or by actual measurement, as the reader desires.) Again, the equation,

$$h_{D6} - h_{C9} = - 2 \rho_d (v_{D6} - v_{C9}) \dots\dots\dots\dots\dots (47)$$

shows that Point C_5 is located at a point on the line through Point D_6 and at a slope, $- 2 \rho_d$, so that the location of Point C_5 is determined in Fig. 13(d), and then projected horizontally to Fig. 13(b) and Fig. 13(c) as indicated. The next point, B_6, is similarly found and, in this case, $A_0 h = B_2 j + B_2 k$; and the line, $h B_6$, is parallel to $A_0 M$. Point B_6 is also located on $A_4 B_6$ at the slope, $+ 2 \rho_a$. Another point, C_7, is obtained by making Line $D_6 l = \overline{B_2 n} + \overline{B_2 m}$, and drawing Line $l C_7$ parallel to Line $g C_5$.

The process is then carried on to the final solution, it being remembered that all A–B lines have a slope, $\pm 2 \rho_a$, all C–D lines, a slope, $\pm 2 \rho_d$, and all B–C lines, a slope, $\pm 2 \rho_b$, or $\pm 2 \rho_c$, depending on whether they belong to Pipe (b) or to Pipe (c). The dimensions of one point, B, and one point, C, are shown, and the drawing made by the method described gives, for B_{10}: $v_{bB10} = 0.74$, $v_{cB10} = 0.82$, and $v_{aB10} = 0.74 + 0.82 = 1.56$; and, for C_9: $v_{bC9} = 0.84$, $v_{cC9} = 0.91$, and $v_{dC9} = 0.84 + 0.91 = 1.75$. In constructing the diagram it is well to check the results frequently by actually measuring the values of v and adding, as in Fig. 13.

Although the pressures at Points A, B, and C, have been found (Points D, of course, lie on the line, $h = 1$), for the first 20 sec, only curves of pressures at Points A and C have been plotted on the separate pressure diagram, Fig. 14, and it shows that Point A reaches the highest pressure at about 12 sec, and the pressure at Point C its maximum value at about 15 sec.

Fig. 14 represents precisely the same piping system as Fig. 13, with the valve at Point A closed in the same manner and time as the former case, but the connection at Point C has been cut off and Pipe (b) plugged. As this case is quite similar to the surge-tank problem, very little explanation will be necessary. In the diagram for Pipe (b) all points, C, must lie on the vertical line, $v_b = 0$, and the pressures at Point C, therefore, rise rapidly; furthermore, the velocities at Point B in Fig. 14(b) change only as much as the elasticity of the water and pipe walls permit, which naturally is not very much. It is like a very small surge tank. In this case, as with the surge tank, $v_{a0} = 1$, $v_{b0} = 0$, and $v_{c0} = 1$. A comparison with the previous case shows that the pressure rise at Points A and C, plotted on Fig. 14, is considerably more in the latter case than in the former, and this agrees with Joukowsky's statement that dead ends aggravate the surge pressures and show the exact amount of such pressures. Fig. 14 is easy to allow for pressure variations at Point D, provided the law of such variation is known, but in that case, of course, the several points, D, would not lie on the one horizontal line. Pressures at any intermediate point in the system are found as with the uniform pipe.

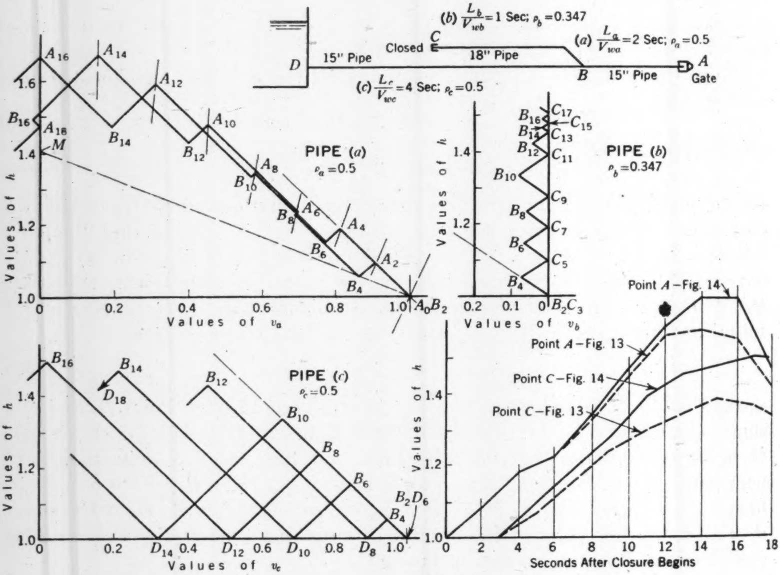

Fig. 14.—Linear Gate Closure in 4 $\left(\frac{2\,L_a}{V_{wa}}\right)$ = 16 Sec; 18-Inch Branch Connected to Main at Only One Point

Pipe with Two Branches Each Discharging Water

Another interesting case is shown in Fig. 15 in which a pipe, $C\,B$, designated by (c) issuing from a fixed level reservoir, has two branches: $B\,A$, marked (*a*); and, *B D*, denoted by (*b*), and discharge is occurring at both Points *A* and *D*. Without going into the details of the pipe dimensions, values have been selected to give a clear drawing, and $\frac{L}{V_w}$ is taken at 1.5 sec for Branch (*a*), 1 sec for Branch (*b*), and 0.5 sec for Line (*c*), whereas the selected values of ρ are 0.5 for Branch (*a*), 0.4 for Branch (*b*), and 0.6 for Line (*c*). It is assumed that the gate at Point *A* is closed by a known law in 6 sec, or two intervals for Pipe (*a*); also that the law of variation between pressure and discharge at Point *D* is known. For example, a turbine may be connected to Point *D* in which the power produced is constant; or some other specified condition may be imposed. In the problem, the law of variation has been assumed as represented by the dotted line on the drawing for Branch (*b*).

Fig. 15.—Gate *A* Has Linear Closure in $2\left(\frac{2L_a}{V_{wa}}\right) = 6$ Sec

This case is dealt with in a manner similar to the others discussed, and, here, $v_{a0} = 1$, $v_{b0} = 1$, and $v_{c0} = 2$. All points, *D*, fall on the dotted line, and the construction need not be explained. The line through A_0 locating Point B_2 has a positive tangent with the data used. The pressure variations at Points *A*, *B*, and *D* are so large and so erratic that it is evidently impossible to use the system in practice. A second case has been developed and illustrated in Fig. 16 for the same system and rate and time of closure of *A*, and the same control at Point *D*, but with the addition of a surge tank at Junction *B*.

This, of course, introduces an extra branch, making four pipes in all, and if the surge tank is denoted by (*d*), then,

$$v_c = v_a + v_b + v_d \dots\dots\dots\dots\dots\dots\dots\dots (48)$$

and $v_{c0} = 2$; $v_{a0} = 1$; $v_{b0} = 1$; and, $v_{d0} = 0$. Using Equation (48) in a method exactly similar to the foregoing, the line, through A_0, is found on the penstock drawing in such a way as to locate Point B_2 from Point $A_{0.5}$, and all points, *B*, on this penstock drawing will lie on lines parallel to Line $A_0 B_2$. Point B_2 is then transferred to the drawings for Pipes (*b*), (*c*), and (*d*) by making them all represent the same pressure and, therefore, Point B_2 is given on each diagram. From Point B_2, Point D_3 is located on Fig. 16(*b*), Point $C_{2.5}$ on Fig. 16(*c*), and Point $E_{2.5}$ on Fig. 16(*d*). It is also evident that Point $B_{2.5}$ lies in each diagram on the same line as Point B_2. Furthermore, at any time (such as 4.5 sec after closure begins) the value of v_c indicated by Point $B_{4.5}$ on Fig. 16(*c*) is the sum of v_a indicated by Point $B_{4.5}$ on Fig. 16(*a*) plus v_b, as shown at Point $B_{4.5}$ on Fig. 16(*b*) plus v_d as given by Point $B_{4.5}$ on Fig. 16(*d*); this is easily checked by measurement.

FIG. 16.—GATE *A* HAS LINEAR CLOSURE IN $2\left(\frac{2\,L_a}{V_{wa}}\right) = 6$ SEC WITH SURGE TANK

Fig. 16 affords an interesting illustration of the effect of the surge tank. In this case the tank has a very small area, being only $\frac{\rho_c}{\rho_a}$, or four times that of Pipe (*c*), and yet it renders the system of Fig. 15 quite practicable as far as the investigation has gone. With no tank, the pressure at Point B after 5 sec is 2.2 times the original pressure, whereas with the tank it is only about 3% above the original level. With no surge tank the fluctuations at Point D up to 5 sec vary from 64% to 158% of normal, a condition that would render any governing mechanism at Point D useless; on the other hand, the surge tank keeps the pressure at Point D within 9% of normal during the first 5 sec. At Point A, the variation in the same time with no surge tank is from 83% to 210% of H_0, whereas the surge tank reduces this variation to 30% of H_0, although at 4 sec it was 48%; and, of course, a larger tank will reduce the variations still further.

This is only a further example of how these difficult problems may be solved simply and accurately, on the drawing board. Although the proportions chosen in the example are most unusual, they serve to make the reduced scale drawings clear, and simplify the method of attack.

PENSTOCK, TURBINE, AND DRAFT-TUBE

A reaction turbine installation, for any but very low heads, consists of a penstock, a turbine with a distributor, and a draft-tube. Water hammer will be produced for every load change, because each change is accompanied by a movement of the distributor gates causing, in turn, an increase or decrease in the volume of water per second being delivered to the turbine; so that the velocities in the penstock and draft-tube change very frequently. It is quite usual to have the gates complete the full opening or closing movement in 2 sec, which corresponds roughly to two intervals in which the penstock is about 1 600 ft long. As a matter of fact, it would correspond to one interval if the turbine happened to be operating at half load, which it suddenly rejected. Governing of such turbines, therefore, may cause high pressures, and the study of this problem will be solved by the graphical method.

Usually, both penstock and draft-tube have a taper, and the method of dealing with compound pipes has already been discussed; but in order to make the diagram simpler, both the penstock and the tube will be assumed to be uniform in size, the draft-tube being the larger and also the shorter. (A method used by Allievi to avoid working with tapering pipes is to assume an equivalent uniform value of V_w from $L = V_w \sum \frac{l_x}{V_{wx}}$. Dr. O. Schnyder has also proposed that an equivalent area may be determined from $A\,L = \sum A_x\,l_x$. In both formulas, l_x, A_x, and V_{wx} refer to the data for the uniform pieces of pipe composing the entire line.[10, 4] Friction and velocity head are not taken into account. The turbine distributor gates serve to cause the varying velocities according to the load demand. In the problem assumed herewith, the dimensions have had to be distorted for clarity, but the diagram to suit any case is easily constructed.

The system is shown on Fig. 17 in which the head, H_0 = 450 ft; Penstock (b) is joined to the forebay at Point C and to the turbine at Point B''; and Draft-Tube (a) carries the water from Turbine B' to the tail-water at Point A; the two points, B' and B'', are assumed close enough together so that the volume of water between them has no effect on the water-hammer pressures. Without more definite data the value of V_w is taken as 3 220 ft per sec in both Draft-Tube (*a*) and Penstock (*b*); the steady velocity, V_0, in the penstock is 4.5 ft per sec; and that in the draft-tube is 3.4 ft per sec. These data give $\rho_a = 0.375$ and $\rho_b = 0.5$, and if the penstock length is 1 290 ft the value of $\frac{L_b}{V_{wb}} = 0.4$ sec. Furthermore, for the purpose of clarity $\frac{L_a}{V_{wa}} = 0.2$ sec (a length of draft-tube which could not be tolerated in practice).

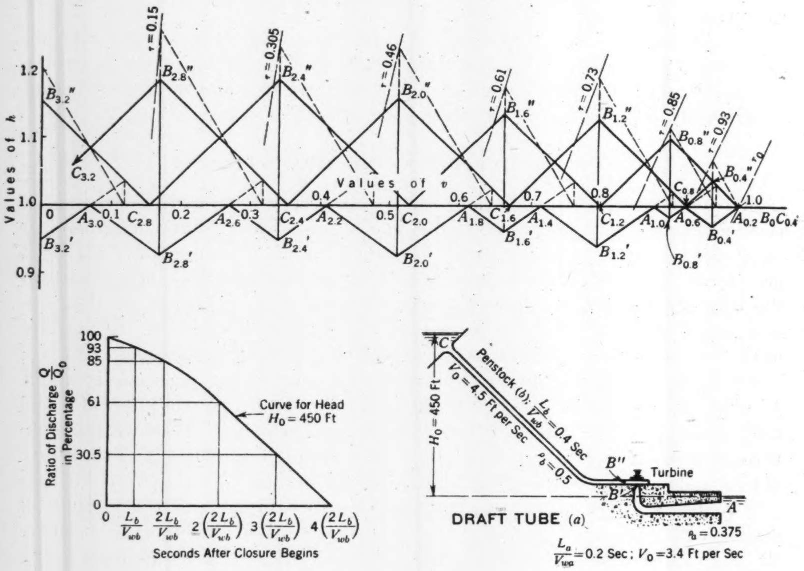

FIG. 17.—GATE CLOSURE IN $4\left(\frac{2\,L_b}{V_{wb}}\right) = 3.2$ SEC

From tests on a large turbine, the curve plotted in Fig. 17, showing the relation between gate position and discharge at normal constant head, has been obtained and there can be little error in assuming that the gate position is a linear function of the time, which has been done in this case; the curve of discharge on a gate-position base, therefore, is also taken to be a curve of discharge on a time base. It is further assumed that closure is effected in 3.2 sec, or in $4\left(\frac{2\,L_b}{V_{wb}}\right)$ sec, which is certainly not unduly short. The time interval in this case must be 0.4 sec, corresponding to the draft-tube value, $\frac{2\,L_a}{V_{wa}} = 0.4$ sec.

Fig. 17 shows the axes of h and v with the point, $h = 1$, $v = 1$, marked $B_0\,A_{0.2}\,C_{0.4}$, since in this case the controlling mechanism is at Point B. Only a few of the equations to be applied will be written (see Equations (26)):

$$h_{C0.4} - h_{B''0.8} = -2\,\rho_b\,(v_{C0.4} - v_{B''0.8}) \ldots\ldots\ldots\ldots (49a)$$

$$h_{B''0.8} - h_{C1.2} = +2\,\rho_b\,(v_{B''0.8} - v_{C1.2}) \ldots\ldots\ldots\ldots (49b)$$

and,

$$h_{B''0.4} - h_{C0.8} = +2\,\rho_b\,(v_{B''0.4} - v_{C0.8}) \ldots\ldots\ldots\ldots (49c)$$

Furthermore, from the corresponding formulas for the pump series:

$$h_{A0.20} - h_{B'0.4} = +2\,\rho_a\,(v_{A0.20} - v_{B'0.4}) \ldots\ldots\ldots\ldots (50a)$$

and,

$$h_{B'0.4} - h_{A0.6} = -2\,\rho_a\,(v_{B'0.4} - v_{A0.6}) \ldots\ldots\ldots\ldots (50b)$$

etc., so that the lines on which Points $B'_{0.4}$ and $B''_{0.4}$ lie are readily found, but their position is not determined. The discharge curve for the turbine, however, shows that at 0.4 sec $= \frac{L_b}{V_{wb}}$, the proportional discharge at the head, H_0, is 0.93, and experience with the action of turbines proves that the flow at a given gate-setting varies with $\sqrt{H_{B''} - H_{B'}}$; that is, with $\sqrt{h_{B''} - h_{B'}}$. A parabola, therefore, is drawn in Fig. 17 with the value, $\tau = 0.93$, and the problem then is to locate $B'_{0.4}$ and $B''_{0.4}$ on the same vertical line (since the value of v is the same at both points at this instant), and having a vertical spacing equal to the height of the parabola, above the axis of v at this same velocity. The reason for this is that $h_{B''0.4} - h_{B'0.4}$ will be the same as the pressure rise to which this velocity corresponds. Schnyder[10] has devised a simple graphical solution to a similar problem by drawing through Point B_0 the dotted line such that its tangent is $2\,(\rho_a + \rho_b) = 1.75$, and where it intersects the parabola, $\tau = 0.93$ is directly above Point $B'_{0.4}$ and Point $B''_{0.4}$. In this manner, these two points are determined and Point $A_{0.6}$ and Point $C_{0.8}$ are found without difficulty (accidentally, they nearly coincide in Fig. 17) since all points, A and C, lie on the line, $h = 1$, if the forebay and tail-water levels do not vary.

The construction for the points, $B'_{0.8}$ and $B''_{0.8}$, is arrived at precisely as before by the aid of the parabola, $\tau = 0.85$, corresponding to the time, $\frac{2\,L_b}{V_{wb}}$, the Schnyder construction being shown by short dots.

Although no definite conclusion can be drawn from the numerical results obtained in this problem (because of the distortion of the dimensions), some comment on the results will be of value. Taking as an example the condition at the turbine 2 sec after closure begins, the values are $h_{B''2} = 1.165$ and $h_{B'2} = 0.93$, which mean that the pressure at the lower end of the penstock has risen 0.165 H_0, or 74 ft above normal, whereas at the top of the draft-tube it has fallen $(1 - 0.93) = 0.07 \times H_0$, or 31.5 ft below normal. Of course, with ordinary plants, the column in the draft-tube would separate with a slightly greater pressure drop than this shows, and the condition in the tube could then be investigated as in one of the problems solved in this paper.

BREACH OF WATER COLUMN DUE TO LOW PRESSURE

A case that has recently come to the writer's attention is illustrated on Figs. 18 and 19, in which a pump discharges through a long pipe line laid with the profile shown. The first part of the pipe slopes somewhat steeply from Valve A at the pump to a point, B, whereas the latter part has a more gentle slope up to the reservoir. The characteristic curve for the pump at its normal speed of $n = 750$ rpm is shown, and the efficiency curve for the machine is also known, as well as the $W R^2$-value of the rotating parts (W = the equivalent weight of the rotating parts and R = its radius). The pump is assumed to be delivering 30 000 000 U. S. gal per day in a pipe in which it produces a velocity of 4 ft per sec. Friction is not considered.

Suppose, now, that the power is suddenly cut off; then the pump begins to slow down, its deceleration depending on the value of $W R^2$ for the rotating parts and on its output; and δn, the decrease in speed, in revolutions per minute in the time, δT, is given by the easily derived formula,[12]

$$\delta n = 183\,540 \frac{Q\,H\,\delta T}{W\,R^2\,e\,n} \quad \text{.................... (51)}$$

in which feet and pounds are the units, and e is the efficiency of the pump.

The method of plotting the characteristic of a pump at any speed, from the curve obtained at some other speed, is well known and need not be explained, and, therefore, the speed corresponding to the characteristic curve passing through any point is readily found. The speed of the pump at any time after disconnecting the power supply can be computed by Equation (51).

The slowing down of the pump causes the pressure to decrease all along the line, and at Point A its value is fixed by the characteristic curve at the reduced pump speed. At very slow speeds, the pressure at Point A is nearly atmospheric unless the pump reverses; the valve at A is assumed to close at the instant the flow reverses. At Point B the low pressure at Point A may produce a pressure much less than the atmosphere, but in this problem a vacuum valve is installed at Point B in such a manner as to prevent the pressure from falling to that extent; that is, the hydraulic gradient at Point B cannot fall below 160 ft above the pump.

Referring to Fig. 18, which has axes of H and V, the starting point is $A_0\,B_1\,C_6$, as marked, and according to Equations (24) the water-hammer line will be drawn through this point, and with a slope, $+\frac{V_w}{g}$. The pump characteristics passing through the point where the water-hammer line intersects the pressure, $H = 160$ ft, corresponds to a speed of 590 rpm and Equation (51) shows that if average values of Q, H, and e, for the period are used, this speed will be reached 0.60 sec after the power is cut off; therefore, Point $A_{0.60}$, which is also Point $B_{1.60}$, is located. In 1.60 sec air begins to enter at Point B and the column parts at that point.

The admission of air and its subsequent release at Point B maintains atmospheric pressure there until the columns re-unite; the original column separates into the two parts, Line $A\ B'$ and Line $B''\ C$, the values of $\frac{L}{V_w}$ for which are, respectively, 1 sec and 5 sec, and it follows, therefore, that Point $B_{1.60}$ also represents the conditions of the upper column for 5 sec after the point, C_6; that is, the velocity at B'' of the upper column remains constant

---

[12] "Water Hammer in Pipes, Including Those Supplied by Centrifugal Pumps," by R. W. Angus, *Proceedings*, Inst. Mech. Engrs., 1937.

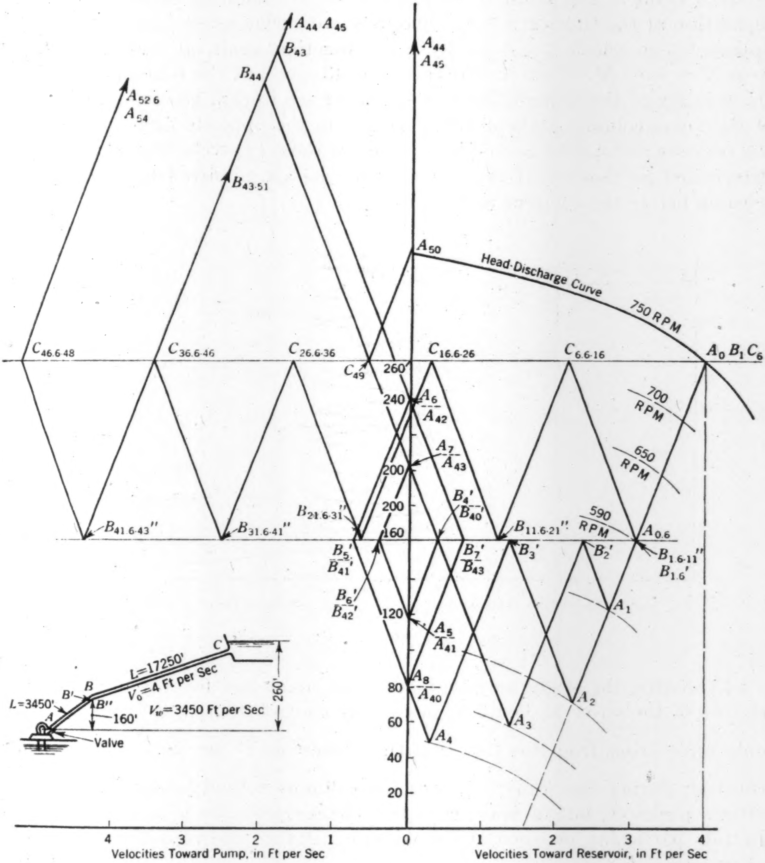

FIG. 18

from 1.6 sec to 11 sec at $V_{B1.6}$. This is readily seen by applying Equations (24) to this case, which give $H_{C6} - H_{B''11} = V_g\,(V_{C6} - V_{B''11})$, so that Point $B''11$ lies on Line $C_6\ A_{0.6}$, and as its pressure is atmospheric, it is fixed at $B'_{1.6} = B''_{1.6}$. The construction already adopted enables one to find Points $C_{6.6-16}$, $B''_{11.6-21}$, etc., and these points are marked on Fig. 18; the location of Points B_2', B_3', etc., give no trouble.

If the valve at Point A is closed in slightly less than 5 sec, the flow through the pump will not reverse and all subsequent values of Point A will lie on the axis of H. On Fig. 19, the velocities at Point B (that is, for Point B' and Point B'') are plotted against time, and it is evident that the hatched area, M, representing an integral of a velocity time diagram gives the linear distance between Point B' and Point B'' at any instant; the columns reach a maximum separation at the time, 21.6 sec, where the two curves cross. After that they approach one another and finally come together again at the time where Area N = Area M, which in this case is at 43 sec. At the time of re-uniting, the velocity of the upper column is 4.4 ft per sec toward the pump, and that of the lower column is about 0.9 ft per sec in the opposite direction, so that the pressure rise will be caused by the sum of these two velocities, and may be determined as shown. It is assumed that the air admitted to the pipe is released before the columns meet again.

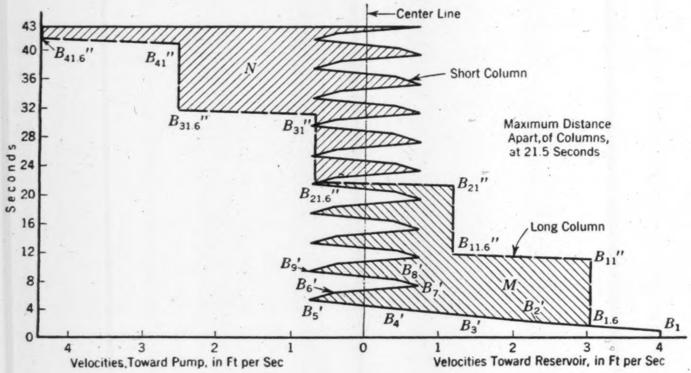

Fig. 19

Evidently, the study may be made with equal ease for any other time of closure of the valve at Point A, or for any control desired at Point B. The only error arises from the fact that the values of $\frac{L}{V_w}$ are assumed to remain constant during the study, whereas the columns actually decrease in length after separation; but in most cases this change produces a very small effect. In this particular problem the maximum distance between the columns is approximately 37 ft.

The odd form of the velocity curve for Point B' is interesting but, of course, the average velocity there could be taken as zero after closure, without affecting the answer. The pressure rise at Point A would be very high and that at Point B_{43} is easily scaled.

In computing values of δn the time intervals must be taken very short and Fig. 19 shows only a few of the points used in the calculation, as the complete set of lines would complicate a small scale drawing.

EFFECT OF FRICTION AND VELOCITY HEAD

The equations necessary to allow for friction and velocity head have been already given and, although the results obtained from them are not exact, they enable closely approximate answers to be obtained in the few cases where these factors are important. In general, it may be said that the friction decreases the bad effects due to water hammer, and computations made by neglecting it are usually on the safe side. In dealing with the problem, it has been frequently assumed that friction loss varies directly with the square of the velocity and, although the calculation may readily be made without this modification, the work is somewhat simplified by it. With this assumption the two quantities, velocity head and friction loss, may be combined into a single term, thus:

$$\text{Velocity head} + \text{friction loss} = \frac{V^2}{2g} + f\frac{L}{D}\frac{V^2}{2g} = V^2\left(\frac{1}{2g}\right) + \frac{f}{2g}\frac{L}{D} = b\,V^2 \quad \text{..(52)}$$

in which the coefficient, b, varies slightly, as f is the only variable in it. To apply this to the h, v-diagram, it must be divided by H_0 and is then written:

$$\frac{b\,V^2}{H_0} = \frac{b\,V_0^2}{H_0}\left(\frac{V}{V_0}\right)^2 = \frac{b\,V_0^2}{H_0}v^2 \quad \text{.............. (53)}$$

which gives the proportional effect on h for each value of v. Thus far, the only known method of allowing for friction loss has been to assume that the total loss is concentrated at certain points along the pipe. In Fig. 20, for example, it has been assumed to be concentrated at two points, B and C; that is, if the friction loss at Velocity V is 12 ft, it is assumed that in each of the obstructions

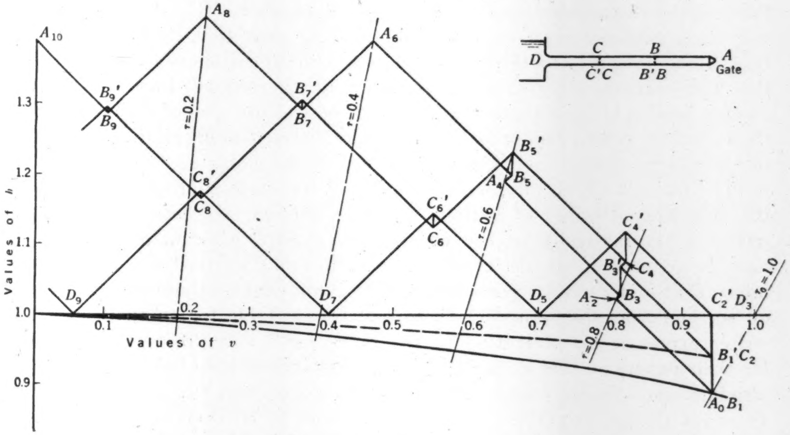

FIG. 20

at Point B and Point C, the loss of head is 6 ft and there is no loss in Pipes $A\ B$, $B'\ C$, and $C'\ D$, each having a length of $\frac{L}{3}$ ft.

With this assumption, each of the parts may be dealt with exactly as in the earlier discussion, but, at any given velocity, Points B and B' must be separated vertically by $b\ \frac{V_0^2}{H_0}\ v^2$, and they must be at the same velocity at the same instant. In Fig. 20 the values $\frac{L}{V_w}$ for each section are the same and are taken as 1 sec $\left(\text{for the entire pipe, } \frac{L}{V_w} = 3 \text{ sec}\right)$; $\rho = 0.5$; and closure is effected in 10 sec, or five intervals of $\frac{2\ L}{V_w}$ sec for the part, $A\ B$. The construction is shown well enough to need little explanation; the curve through $v = 0$, $h = 1$, and A_0 is separated from the axis of v by $\frac{b\ V_0^2\ v^2}{H_0}$; and the dotted line, which represents the loss at each obstruction, is half-way between the axis of v and the curve. Each pair of points, $B\ B'$, $C\ C'$, is separated vertically by the distance from the axis of v to the dotted curve corresponding to the velocity, v.

Conclusion

The variety of the illustrations shows that the method is not only quick, but is easily applied to problems met in practice. Knowing the starting point on the diagram and the law of operation of the valve or other device causing the pressure disturbance, one can solve the problems easily. A variable reservoir level introduces no trouble and merely means that such points as D (Fig. 11) no longer lie on the line $h = 1$ or H_0, but at distances above and below this line, corresponding to the variation from the original level. When the friction head is large compared with H_0 it is best to use axes of H and V rather than h and v, and to choose scales that make distinct intersections of the lines; but a little practice gives one much guidance in the plotting.

The method avoids the tedious tracing of the various pressure waves, and the complicated study of various reflection factors, as these have all been included automatically in the construction. Such experimental studies as have been made available, check the accuracy of the construction, but it is hoped that many more experiments will be conducted by those who are able to do so, and that the results of these will be available for comparison. The writer expresses his obligation to Dr. Schnyder,[10] and Professor Bergeron,[11] for their papers on this work and for the illustrations they have given. He is also indebted to many other authors and to the excellent paper on "High Head Penstock Design," by Messrs. A. W. K. Billings, O. H. Dodkin, F. Knapp, and Adolpho Santos, presented on June 30, 1933, under the joint auspices of the Hydraulic Division, A. S. M. E., and the Power Division, Am. Soc. C. E.[13]

APPENDIX

NOTATION

The following symbols, as defined in the paper where they first appear, conform essentially with "Symbols for Hydraulics" compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1929:[14]

A = area of a pipe, a subscript designating the pipe referred to; A_g = area of a gate-opening; $A_{4.5}$ = a point on the diagram representing both the pressure and velocity at Point A on the pipe at 4.5 sec after water hammer begins;

$B = \dfrac{c_d\, A_g\, \sqrt{2\, g}}{A_a}$ and is a function of effective gate area $= c_d\, A_g$; B_0 = the value of B for the initial, steady flow condition;

b = a coefficient (see Equation (52));

c_d = coefficient of discharge;

D = inside diameter of pipe;

E = Young's modulus for the material in the pipe;

e = efficiency of pump;

F = short form for $F\left(T - \dfrac{x}{V_w}\right)$, is the magnitude of a direct wave at time, T, and at x ft from gate; F_n = magnitude of a wave in its nth movement; F_1 = magnitude of a wave at the end of the first movement;

f = short form for $f\left(T + \dfrac{x}{V_w}\right)$, is the magnitude of a reflected wave at time, T, and at x ft from the gate;

g = acceleration due to gravity;

H = general term for pressure head at a given time and place on the pipe; H_0 = initial pressure head at the gate under steady flow conditions; H_{BT_2}, etc. = head at Point B on the pipe (Fig. 8) at the time, T_2 sec after gate movement begins; H_A = head at Point A, usually at the point of disturbance;

h = pressure head change; δh = small pressure head change; also, h_{BT_2} etc. = ratio $\dfrac{H_{BT_2}}{H_0}$, etc.; h_r = friction loss in feet;

K = bulk modulus of elasticity of the liquid;

L = length of pipe, or the distance traveled by a wave;

l = short length of uniform diameter in a tapering pipe;

m = mass of the water changed in velocity;

n = speed of the rotating part of a centrifugal pump and motor, in revolutions per minute; δn = a decrease in speed;

p = pressure intensity at any point in a pipe line, due to water;

Q = discharge; Q_0 = a uniform steady discharge;

---

[14] A. S. A.—Z10b—1929.

R = effective radius of the rotating parts of a centrifugal pump and motor;

T = time; δT = short interval of time; also, δT = time required for a decrease in speed of δn;

t = thickness of a pipe;

V = average velocity; V_0 = steady, uniform velocity; V_w = velocity of pressure wave; δV = velocity extinguished; V_1 = velocity reached at the end of the first interval; V_2 = velocity reached at the end of the second interval; V_{BT2} = velocity at the Point B on the pipe at the time, T_2, after disturbance begins; V_A = velocity at Point A; v_{BT2} = a ratio, $\frac{V_{BT2}}{V_{B0}}$, etc.;

W = equivalent weight of the rotating parts of a centrifugal pump and motor;

w = weight of 1 cu ft of water;

x = variable distance along a pipe measured from the gate;

y = piezometer pressure reading at Point x during water hammer; y_0 = piezometer pressure reading at Point x under steady flow conditions;

z = height of any point, x, above the gate;

α = slope angle of a pipe;

ρ = pipe line characteristic = $\frac{V_w V_{A0}}{2 g H_0}$;

τ = a function of time (see Equation (30*b*)) = $\frac{v_A}{\sqrt{h_A}} = \frac{B}{B_0}$.

DISCUSSION

K. J. DEJUHASZ,[15] ESQ. (by letter).—For the purpose of analyzing complicated inter-relationships, the graphical method is far superior to numerical computations. The writer's experience with water-hammer is based not on water conduits, but on fuel-injection systems of Diesel engines. These types also involve complicated water-hammer phenomena for which numerical computations are scarcely practicable, although they can be analyzed readily by graphical methods. Therefore, the writer fully endorses the author's preference for the graphical method.

The examples given in this paper treat important practical cases and are highly instructive. In the writer's opinion, however, their clarity would be enhanced by a supplementary diagram, with time as the abscissa and distance as the ordinate, showing when and where the v and h-flow conditions exist. Indexing the v and h-points, as was done by the author, is helpful, but does not tell the entire story. Such distance *versus* time diagrams are easily constructed if the acoustic velocity for the various pipe subdivisions are known. It is admitted, however, that for knowledge of the absolute magnitude of the surge pressure (and this is the most important question), the v, h-chart alone is sufficient.

In dealing with fuel-injection phenomena the writer has also been confronted by the question as to how to represent the pipe friction in the diagram. The author's approach appears workable, but it is open to the objection that the friction is assumed to be localized at definite points in the pipe, whereas actually it is distributed all along the pipe. As yet the writer cannot suggest any definite procedure that would more closely approach the actual conditions. It seems, however, that the friction could be taken into account by varying the slopes of the directrix, that is, using a directrix of greater slope when pressure is converted into velocity (because the frictional resistance absorbs part of the pressure energy), and using a directrix of smaller slope when velocity is converted into pressure (because the frictional resistance absorbs part of the velocity energy). Admittedly, such a method would be handicapped by some complications that the author's simplified procedure does not involve, and it is offered solely as another line of attack along which the solution of this question might be attempted.

Transient phenomena in elastic columns constitute a wide group, including, in addition to water-hammer, spring surges, surges in gas columns, and electric transients, all having important applications in engineering. The graphical analysis appears to be a highly useful tool. It is to be hoped that Professor Angus' scholarly paper will help to direct attention to the advantages of the graphical method and serve as an incentive to its application in related engineering fields.

---

[15] Associate Prof., Eng. Research, The Pennsylvania State Coll., State College, Pa.

Harold A. Thomas,[16] **M. Am. Soc. C. E.** (by letter).—American hydraulic engineers have been rendered a notable service by the publication of this clean-cut and workable graphical method for solving problems of water-hammer in branching and compound pipes. While studying this method the writer has noted that Professor Angus is not correct in stating that the solution of these problems by analytical means is almost impossible (see "Synopsis"). The fundamental equations underlying the method lead to a convenient analytical solution which gives the same results as the graphical one.

Since numerical methods of computation have certain advantages over graphical ones, it seems desirable to present a brief outline of the analytical method for solving problems of the type under consideration. Among the advantages of the analytical method may be mentioned the possibility of obtaining high accuracy by the use of computing machines, the convenience of checking by another person, the keeping of the work on sheets of convenient size for filing and incorporation in reports, freedom from troubles due to paper shrinkage and wrinkling, and freedom from trouble due to having the work extend beyond the boundaries of the paper. In important cases, each method should give a valuable check on the other.

In general, the analysis is applicable to problems involving a valve or gate of variable opening, connected to a group of uniform pipes of various lengths and diameters, these pipes being joined together by two-way or three-way junctions. Before starting the computation, a sketch of the system should be made, each end of each uniform pipe designated by a letter, and an arrow marked on each uniform pipe to indicate the assumed positive direction of flow in that pipe. This direction may be assumed arbitrarily, except that in the case of two pipes in series both arrows must point in the same direction, and in the case of a three-way junction all three arrows must not point either toward or away from the intersection. In certain pipes of the system the flow will have a known direction under a condition of steady discharge with the gate or valve open, and it is convenient to make this the positive direction of flow for those pipes.

Notation Pertaining to a Frictionless Uniform Pipe.—The notation to be used herein will follow that of the author, with some necessary amplifications. The flow is assumed to be frictionless except where otherwise mentioned. The analytical work is materially simplified by presenting the equations in terms of discharge rather than velocity. A = area of cross-section; V_w = velocity of acoustic wave; T = time to any given instant; $T' = T - \frac{L}{V_w}$ = time to an instant, $\frac{L}{V_w}$ sec earlier; X designates that end of the pipe at which the head and discharge are unknown at a given instant, T; X' designates the other end of the pipe where the head and discharge are known at the earlier instant, T'.

In the following notation for head and discharge the simpler or abbreviated symbols can be used in cases where no ambiguity results:

---

[16] Prof., Dept. of Civil Eng., Carnegie Inst. of Tech., Pittsburgh, Pa.

Symbol		Definition
H, H_X, or H_{XT}	=	head at Section X, at time, T.
Q, Q_X, or Q_{XT}	=	discharge at Section X, at time, T.
H', H'_X, or $H_{X'T'}$	=	head at Section X', at time, T'.
Q', Q'_X, or $Q_{X'T'}$	=	discharge at Section X', at time, T'.

The term, "head," at any section of a pipe is used herein to designate the elevation of the center of the pipe above the datum, plus the pressure head at the center of the pipe.

Finally, N = a factor whose value is $+1$ or -1 according to whether the positive direction of flow in the given uniform pipe is toward X or away from X; $S = \frac{N\,V_w}{g\,A}$ = slope of a line in graphical construction (see Fig. 23); and, C = a water-hammer constant, such that,

$$C = H + S\,Q = H' + S\,Q' \qquad (54)$$

Notation Pertaining to a Valve or Gate.—If the gate discharges into the open air, take the datum plane through the *vena contracta* of the jet, and let H and Q be the head and discharge, respectively, just above the gate, whose coefficient of discharge is C_d and whose area of opening is A_g. Then, $Q = C_d\,A_g\,\sqrt{2\,g\,H} = k\,\sqrt{H}$, or,

$$H = \frac{Q^2}{k^2} \qquad (55)$$

in which k is a known function of the time, T.

If the gate discharges under water, assume the datum plane arbitrarily, and let H_X and H_Y be the heads just up stream and down stream from the gate, respectively. In cases where $H_X - H_Y$ is positive, Equation (55) then becomes,

$$Q = k\,\sqrt{H_X - H_Y} \qquad (56)$$

In order to provide for cases in which the flow through the gate may be reversed so that Q and $H_X - H_Y$ become negative, the relation may be generalized to read: $Q = \frac{k\,(H_X - H_Y)}{\sqrt{|\,H_X - H_Y\,|}}$ or,

$$H_X - H_Y = \frac{Q\,|\,Q\,|}{k^2} \qquad (57)$$

in which the symbol, $|\;|$, enclosing a given quantity designates the absolute (positive) numerical value of that quantity.

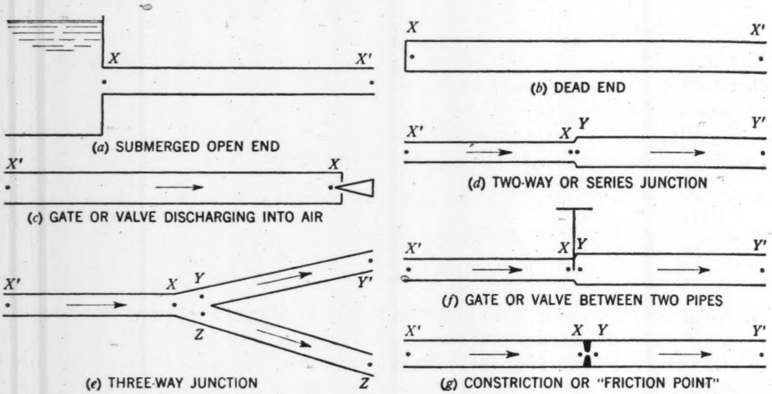
General Relation Between Head and Discharge in a Frictionless Pipe in Which Waves of Pressure Change Are Present.—According to the principles derived in Professor Angus' paper the head, H_{XT}, and the discharge, Q_{XT}, are related as follows to each other and to the head, $H_{X'T'}$, and discharge, $Q_{X'T'}$:

$$H_{XT} + \frac{N\,V_w}{g\,A}\,Q_{XT} = H_{X'T'} + \frac{N\,V_w}{g\,A}\,Q_{X'T'} = \text{constant} \qquad (58)$$

In the foregoing abbreviated notation, this relation may be written:

$$H + S\,Q = H' + S\,Q' = C \qquad (59)$$

The following paragraphs give the application of this general formula to a variety of special cases.



(a) SUBMERGED OPEN END

(b) DEAD END

(c) GATE OR VALVE DISCHARGING INTO AIR

(d) TWO-WAY OR SERIES JUNCTION

(e) THREE-WAY JUNCTION

(f) GATE OR VALVE BETWEEN TWO PIPES

(g) CONSTRICTION OR "FRICTION POINT"

FIG. 21

Submerged Open End; Fig. 21(*a*).—In this case since the head in the open water of the tank or reservoir is always equal to H_0 the head at X at any instant, T, is given by $H = H_0$. Moreover, by Equation (59), $H_0 + S\,Q = C$. Therefore, the discharge at Section X at any instant, T, is given by,

$$Q = \frac{C - H_0}{S} \qquad (60)$$

Dead End; Fig. 21(*b*).—In this case the discharge past the dead end is zero at all times. Therefore, the discharge at Section X at any instant, T, is given by $Q = 0$; also, by Equation (59), the head at X at the instant, T, is given by:

$$H = C \qquad (61)$$

Valve or Gate Discharging into Air; Fig. 21(*c*).—The datum plane is taken through the *vena contracta* of the jet. In this case by Equation (59) and Equation (55):

$$H + S\,Q = C \qquad (62a)$$

and,

$$H = \frac{Q^2}{k^2} \qquad (62b)$$

Therefore, the discharge at Section X at any given instant, T, is given by:

$$Q = \frac{S\,k^2}{2}\left(\sqrt{1 + \frac{4\,C}{S^2\,k^2}} - 1\right) \qquad (63a)$$

and the corresponding head is given by,

$$H = C - S\,Q \qquad (63b)$$

Two-Way or Series Junction; Fig. 21(*d*).—Neglecting the effects of velocity head and energy losses due to sudden contraction or expansion, the head at the junction is the same whether the junction is considered a part of Pipe $X'\,X$, or of Pipe $Y\,Y'$. Therefore, let $H = H_X = H_Y$. Assuming that the positive direction of flow has been chosen the same in both pipes, the law of continuity of flow may be written: $Q = Q_X = Q_Y$. Also, by Equation (59),

$$H + S_X\,Q = C_X \qquad (64a)$$

and,

$$H + S_Y\,Q = C_Y \qquad (64b)$$

Therefore, the discharge and head at the junction at any given instant, T, are given by:

$$Q = \frac{C_X - C_Y}{S_X - S_Y} \qquad (65a)$$

and,

$$H = C_X - S_X\,Q \qquad (65b)$$

Three-Way Junction; Fig. 21(*e*).—Neglecting the effects of velocity head and energy losses due to expansion or contraction, the head at the junction is the same whether the junction is considered a part of Pipe $X'\,X$, Pipe $Y\,Y'$, or Pipe $Z\,Z'$. Therefore, let $H = H_X = H_Y = H_Z$. Assuming that all three arrows do not point either toward or away from the junction, and that the points, X, Y, and Z, are chosen so that branches Y and Z are the two in which the positive directions of flow with respect to the junction are the same, the law of continuity of flow takes the form: $Q_X = Q_Y + Q_Z$. By Equation (59), $H + S_X\,Q_X = C_X$; $H + S_Y\,Q_Y = C_Y$; and, $H + S_Z\,Q_Z = C_Z$. Therefore, at any given instant the head at the junction is given by,

$$H = \frac{\dfrac{C_X}{S_X} - \dfrac{C_Y}{S_Y} - \dfrac{C_Z}{S_Z}}{\dfrac{1}{S_X} - \dfrac{1}{S_Y} - \dfrac{1}{S_Z}} \qquad (66)$$

and the discharges in the three branches are given by,

$$Q_X = \frac{C_X - H}{S_X} \qquad (67a)$$

$$Q_Y = \frac{C_Y - H}{S_Y} \qquad (67b)$$

and,

$$Q_Z = \frac{C_Z - H}{S_Z} \qquad (67c)$$

Gate or Valve Between Two Pipes; Fig. 21(*f*).—In this case it is considered that the positive direction of flow has been assumed the same in both pipes, and that X and Y are so chosen that the positive direction of flow is from X to Y. Then, at any instant, T, the discharge through the gate is $Q = Q_X = Q_Y$. It follows from Equations (57) and (64) that, at any instant, T, the discharge through the gate is given by:

$$Q = \frac{k^2 (S_X - S_Y)}{2} \frac{(C_X - C_Y)}{|C_X - C_Y|} \left(\sqrt{1 + \frac{4|C_X - C_Y|}{k^2 (S_X - S_Y)}} - 1 \right) \ldots\ldots (68)$$

and the heads just above and below the gate are given by,

$$H_X = C_X - S_X Q \ldots\ldots (69a)$$

and,

$$H_Y = C_Y - S_Y Q \ldots\ldots (69b)$$

Friction Point; Fig. 21(g).—The approximate friction loss, H_f, in any uniform pipe is considered to be $j\,Q^2$, in which Q is the discharge at the middle of the pipe at the given instant and j is the coefficient of Q^2 in the ordinary pipe-friction formula,

$$H_f = f \frac{L}{D} \frac{V^2}{2\,g} = f \frac{L}{D} \frac{Q^2}{2\,g\,A^2} \ldots\ldots (70)$$

For purposes of computation the loss is assumed to be concentrated in a very short distance, $X\,Y$, at the mid-section of the pipe, the letters being so chosen that the positive direction of flow is from X to Y. Therefore, $Q = Q_X = Q_Y$ and $S = S_X = -S_Y$. In order to provide for possible reversal of the direction of flow in the pipe, the relation between lost head and discharge is written in the generalized form, Equation (57), $H_X - H_Y = j\,Q|Q|$. By Equation (64), $H_X + S\,Q = C_X$ and $H_Y - S\,Q = C_Y$. Therefore,

$$Q = \frac{S\,(C_X - C_Y)}{j\,|C_X - C_Y|} \left(\sqrt{1 + \frac{j\,|C_X - C_Y|}{S^2}} - 1 \right) \ldots\ldots (71)$$

$$H_X = C_X - S\,Q \ldots\ldots (72a)$$

and,

$$H_Y = C_Y + S\,Q \ldots\ldots (72b)$$

It is to be noted that the effect of a "friction point" is exactly the same as that of a constriction at the mid-section of the pipe. If it is desired to compute the friction loss in a uniform pipe with more refinement than this, the pipe may be regarded as divided into several segments and a "friction point" located at the middle of each. The value of j for each segment will then be based on the length of that segment. If two segments of equal length are used, the two constrictions producing the friction loss will thus be located at the quarter-points of the original pipe. Professor Angus' method of finding the friction head for this case, as shown in Fig. 20, is slightly different from the foregoing, his two constrictions being at the one-third points instead of at the quarter-points. Where several segments are used, the method outlined herein is more accurate than that used by Professor Angus, since it makes the stepped hydraulic grade line conform more closely to the true linear hydraulic grade line. However, in many problems, the difference of the results obtained by the two methods would be inappreciable.

Solution of Problems.—The foregoing equations are sufficient for the solution of all ordinary problems of water-hammer in compound and branching pipes. The work is greatly facilitated by tabulating the numerical quantities in a systematic manner. A suitable arrangement for the computations is suggested in the following illustrative problem. In general, a separate table must be arranged for each of the following kinds of points occurring in the given pipe system: submerged open end, dead end, valve or gate, series junction, and three-way junction. If the effects of friction are to be considered, one or more "friction points" are placed in each uniform pipe, and a table is included for each of these points.

When the blank tables have been prepared and the initial values of head and discharge have been written into the tables in their proper places, the remainder of the computation becomes automatic. The values of head, H, and discharge, Q, computed in one table for a given instant, T, at one end of one of the uniform pipes, can always be inserted in another table as the values of H' and Q' for the abutting end of an adjacent uniform pipe. Repetition of this process solves the problem.

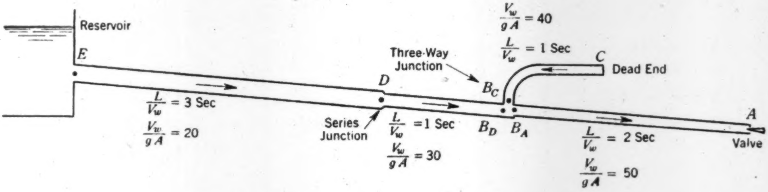


FIG. 22.—DATA FOR ILLUSTRATIVE PROBLEM

Illustrative Problem.—For this problem (see Fig. 22) $H_0 = 100$ ft; and $Q_0 = 10$ cu ft per sec; therefore, $k_0 = \frac{Q_0}{\sqrt{H_0}} = 1$. The valve is closed at a uniform rate in 10 sec; and, therefore, $k = 1 - \frac{T}{10}$. Values of head and discharge are to be computed at 2-sec intervals at the various sections designated by letters in Fig. 22. Friction is neglected. For this problem the foregoing general formulas reduce to the following special ones:

For Section A, a valve discharging into air, $X = A$; $X' = B_A'$; $N = 1$; $S = 50$; $C = H' + 50\,Q'$; and $k = 0.1\,(10 - T)$:

$$Q = 25\,k^2\left(\sqrt{1 + \frac{C}{625\,k^2}} - 1\right) \ldots\ldots\ldots\ldots\ldots (73a)$$

and (see Equations (63)),

$$H = C - 50\,Q \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (73b)$$

Equations (73) are solved in Table 1.

4	Head, H (Item (3) plus Item (2))	135.1	171.3	225.6
5	Discharge, Q	0	0	0
Item No.	Section-instant X T	C 5	C 7	C 9

For Section D, a series junction:

$$\begin{array}{llll} X = D_E; & Y = D_B; & C_X = H'_X + 20\,Q'_X; \\ X' = E; & Y' = B_D; & C_Y = H'_Y - 30\,Q'_Y; \\ N_X = 1; & N_Y = -1; & \\ S_X = 20; & S_Y = -30; & \text{and (see Equations (65)):} \end{array}$$

$$Q = \frac{C_X - C_Y}{50}; \qquad \text{and,} \qquad H = C_X - 20\,Q.$$

The solution of these formulas is given in Table 4.

For Section E, a submerged open end, at reservoir: $X = E$; $X' = D$; $N = 1$; $S = -20$; $C = H' - 20\,Q'$; $H = 100$; and (see Equation (60)), $Q = \dfrac{C - 100}{-20}$. The solution is arranged as in Table 5.

Tables 1 to 5 are arranged so that the known values, Q' and H', appear at the top of each column and the unknown values, Q and H, appear at the bottom. The term, "section-instant," is used to denote a given place and time. Thus, in Table 5, at the section-instant D 5, the discharge, Q', is 9.30 cu ft per sec. The letter at the bottom of the first numerical column in each table designates the given section, and the numeral designates the instant 2 sec after the

first impulse from the valve movement reaches the given section. For example, at Section E the initial conditions remain unchanged for 6 sec after the valve movement begins. Therefore, in the table for Section E (Table 5) the symbol, E 8, is written at the bottom of the first numerical column. The numerals at the bottom of the remaining columns (or groups of columns) of each table increase by 2-sec increments. The letters and numerals at the top

Item No.	Section-instant $X\ T$......................	E 8	E 10	E 12

of each column are determined from those at the bottom. Thus, in Table 5, the symbol, D 5, is written at the top of the first numerical column, because Section D is at the far end of the uniform pipe terminating in Section E, and an impulse requires 3 sec to travel from D to E.

The computation is started by writing into the tables the known initial head of 100 ft for section-instants, B_A 0, B_A 2, C 3, D 3, E 2, E 4, E 6, E 8, E 10, and E 12; the known initial discharge of 10 cu ft per sec for section-instants, B_A 0, B_A 2, D 3, E 4, and E 6; and the known initial discharge of 0 cu ft per sec for section-instants, C 3, C 5, C 7, and A 10.

The values of head and discharge are now computed for all the remaining section-instants in the following order:

A 2	B_A 4	B_C 4	B_D 4	C 5	D 5	E 8
A 4	B_A 6	B_C 6	B_D 6	C 7	D 7	E 10
A 6	B_A 8	B_C 8	B_D 8	C 9	D 9	E 12, etc.

A schedule for each individual computation is indicated in the tables. The numerical work in this example has been extended to the tenth second at Section A, and by means of the same process it can be carried to any desired subsequent even second.

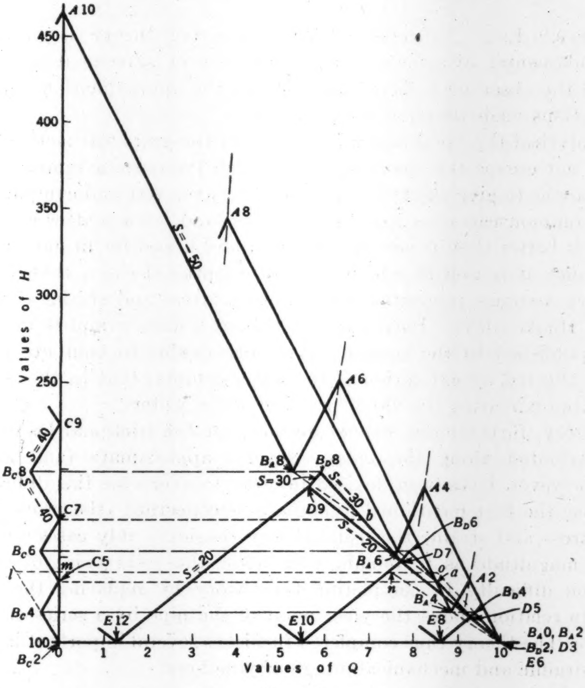

FIG. 23

Comparison with Graphical Solution.—A solution of the foregoing problem by Professor Angus' graphical method, slightly modified, is shown in Fig. 23. It is seen that the analytical and graphical methods give identical results. In this diagram the abscissas are plotted in terms of discharge rather than of velocity, in conformity with the principle given in Equation (59). This device of expressing the flow in terms of discharge rather than velocity is very helpful in clarifying the general analysis of water-hammer problems in compound and branching pipes, since it eliminates the use of complicated velocity relationships such as those described by the author in connection with Equation (37). However, it does not change the shape of the final graphical figure.

Professor Angus is to be complimented especially on the elegance of his graphical solution for the problem of the three-way junction. Practice in the use of this device suggests modifications for cases in which the construction falls beyond the boundaries of the paper. Such a modification is shown in Fig. 23. On the arbitrarily located horizontal line, *ol*, lay off *on* equal to *ml* and draw a line from D 3 to n. The direction of the latter line defines the direction of the lines which solve the three-way junction problem by joining D 3 to B_A 4, a to B_A 6, and b to B_A 8.

F. Knapp,[17] Esq. (by letter).—All engineering theory is based upon certain fundamental hypotheses, and the degree of agreement between the theory and the observed behavior depends on the approximation with which the assumptions made describe the actual facts.

The analytical theory of water-hammer and the graphical method derived from it do not escape this necessity. Although the basic assumptions are of such a nature as to give excellent agreement between test and computation for the more common cases occurring in practice (and, as a matter of fact, this agreement is better than is actually required and hoped for in most hydraulic computations), it is well to remember, for exceptional cases, that the elastic surge theory assumes proportionality between stress and strain; that is, the validity of Hooke's law. Furthermore, without a more complete theory than has been published to the present, it is not possible to compute the surge conditions affected by cavitation of the water-column; that is, the subnormal pressures approximating the vapor pressure of the water.

The theory, furthermore, cannot account for the frictional losses as they occur, distributed along the pipes. Several approximate (and graphical) methods, however, have been devised in order to overcome this difficulty.

As far as the first mentioned hypothesis is concerned (the proportionality between stress and strain) the usual theory considers only cases with surges of such a magnitude as to remain well below the yield point of the pipes. There is no difficulty in completing the theory by replacing the observed stress-strain relation above the yield point of the pipe by a series of tangents or secants. The theory thus completed furnishes several important indications for the hydraulic and mechanical design of pipe lines.

The author's example of the "breach of the water column due to low pressures" is based on several assumptions that are neither corroborated by experimental verification nor by a careful examination of the subnormal pressure conditions in the pipe line. As stated by the author, the graphical method avoids the tedious tracing of the various pressure waves and the complicated study of various reflection factors, as these have all been included automatically in the construction. It is just this facility of the construction which may lead to considerable errors and for this reason the writer[13] treated, at length, the surge conditions in a pipe line by means of reflection and transmission factors combined with the "wave-plan." Although tedious, such a study represents an excellent basis for the complete understanding of the graphical method of surge computations.

---

[17] With the São Paulo Tramway Light & Power Co., São Paulo, Brazil; Assoc. Member, Waterhammer Committee, A. S. M. E., representing Brazil.

Referring to Fig. 18 of the paper, the line connecting the points, $A_{0.6}$ and $C_{6.6-16}$, indicates a negative pressure wave with a magnitude of 100 ft; the author assumes this wave to travel up the flatter part of the pipe line without causing disturbances of any kind. He also assumes this wave to be reflected totally, but with opposite sign, at the intake. According to Fig. 18, the pressure head at the intake is only a small fraction of the magnitude of the negative surge wave and this means that the water column between Sections B and C is subject to cavitation conditions. It follows, also, that the maximum subnormal pressure in the upper flatter section of the pipe line for any section cannot be greater than the difference between the static water level and the elevation head of the section considered and an additional amount given by the prevailing barometric pressure minus the vapor pressure of the water. The wave thus travels up the line with diminishing magnitude in accordance with the profile of the pipe line. As a consequence, the reflection at the intake occurs with only a fraction of the original wave.

The column of water, subject to subnormal pressure conditions, releases, partly, the air contained in it. When the wave returns, the elastic properties are found to have changed to such an extent that the surge velocity is considerably less than before. Again, reaching Section B, the original pressure conditions are being restored, and it should be noted that during this process the atmospheric pressure plays an important part.

The author assumes that Section B represents a point of total reflection and, consequently, treats the two columns, $A\,B'$ and $B''\,C$, separately. This assumption is not justified; nor has it been corroborated by actual experimental verification. The conditions in the pipe line occur in accordance with simple physical considerations as described herein. Without anticipating the results of a probable future publication regarding this special aspect of the theory of water-hammer, the writer would remark that it is not surprising to find that an approach to a difficult problem such as that presented by the author (under assumptions that are fundamentally incorrect) gives results in accordance with these assumptions.

In 1935, the writer called attention[18] to the incorrect solution of the problem under discussion, first proposed by O. Schnyder,[19] later, by M. L. Bergeron,[20] and now reviewed by the author.[21]

[18] "Ueber eine allgemeine graphische Berechnungsmethode der Druckstoesse in Rohrleitungen," by F. Knapp, *Wasserkraft und Wasserwirtschaft,* 1935, p. 279; also, "Operation of Emergency Shut-Off Valves in Pipelines," by F. Knapp, *Transactions,* A. S. M. E., November, 1937.

[19] "Ueber Druckstoesse in Rohrleitungen," by O. Schnyder, *Wasserkraft und Wasserwirtschaft,* 1932, p. 49.

[20] "Pompes centrifuges e usines elevatoires," by M. L. Bergeron, *La Technique Moderne,* 1935, No. 5.

[21] The same criticism applies to the author's paper, "Air Chambers and Valves in Relation to Waterhammer," *Transactions,* A. S. M. E., November, 1937.

Referring to the text following Equation (40), it may be interesting to indicate the solution of branch-pipe problems in a different manner. Simultaneous equations for Branches (*a*) and (*c*) may be written as follows:

$$h_{At-2} - h_{aBt} = 2\,\rho_a\,(v_{At-2} - v_{aBt}) \quad\ldots\ldots\ldots\ldots\ldots(74a)$$

and,

$$h_{Ct-4} - h_{cBt} = -\,2\,\rho_c\,(v_{Ct-4} - v_{cBt}) \quad\ldots\ldots\ldots\ldots\ldots(74b)$$

From Equation (74*a*) it follows that:

$$v_{aBt} = v_{At-2} - \frac{1}{2\,\rho_a}\,(h_{At-2} - h_{aBt}) \quad\ldots\ldots\ldots\ldots\ldots(75a)$$

and, from Equation (74*b*):

$$v_{cBt} = v_{Ct-4} + \frac{1}{2\,\rho_c}\,(h_{Ct-4} - h_{cBt}) \quad\ldots\ldots\ldots\ldots\ldots(75b)$$

Introducing Equations (75) into the equation of continuity and considering, also, the relation expressed by Equation (35), the following is obtained:

$$\left(\frac{\rho}{\rho_a}\,h_{At-2} + \frac{\rho}{\rho_c}\,h_{Ct-4}\right) - h_{Bt} = -\,2\,\rho\,\left[(v_{At-2} + v_{Ct-4}) - v_{bBt}\right] \ldots(76)$$

in which,

$$\rho = \frac{\rho_1\,\rho_2}{\rho_1 + \rho_2} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(77)$$

Equation (76) has exactly the same structure as the simultaneous Equations (26). The slope of the line, defined by $-\,2\,\rho$, is constant and equal to that of the line, $A_0\,M$, in Fig. 12. As a matter of fact, Equation (76) represents a momentary "end condition," replacing the two branches, (*a*) and (*c*), temporarily, by a single line. In practice, and in order to speed up the application, it is more convenient to start the line with the slope, $-\,2\,\rho$, at a point corresponding to the velocity in the surge tank at the wye with the pressure-ordinate, $h = 1.0$, instead of computing the starting point of this line by means of Equation (76). This relation, of course, may be extended so as to be applicable to any number of branches, meeting in one single point.

The treatment of the draft-tube problem, given by the author, is most interesting. The writer would only remark that, in practice, the change of the speed of the unit would also have to be considered in the computation.

As far as the "large and erratic" pressure variations at Points *A*, *B*, and *D* of Fig. 15 are concerned, it becomes evident from a closer study that this unsatisfactory behavior is due to the unstable characteristic of the valve at Section *D*, assumed by Professor Angus. Certain valves exist with such a head-velocity relation, but in practice the effect is not as pronounced as is assumed in Fig. 15. It is certainly not desirable, as proposed by the author, to make such an installation stable by the addition of a stand-pipe or surge tank, because the engineer who designs such a layout would choose a valve with a satisfactory characteristic.

In spite of the fact that he treats the basic relations in considerable detail, the author still uses the old-fashioned method of developing Equations (10) by means of differential equations. Their development, by simple physical considerations, was demonstrated by the writer in 1937.[22]

In spite of the writer's criticism of the paper, the author deserves the thanks of the profession for having brought to the attention of a greater circle of engineers a subject of lively interest, heretofore limited to a small number of specialists.

Martin A. Mason,[23] Jun. Am. Soc. C. E., Pierre F. Danel,[24] Assoc. M. Am. Soc. C. E., and Antoine Craya,[25] Esq. (by letter).—There are a few points of importance omitted from Professor Angus' excellent paper which should be discussed as concerning the accuracy of the graphical method and as showing a further liaison between it and the analytical method of studying water-hammer phenomena.

Consider, first, the case of a compound pipe consisting of a number of dicontinuities provided by changes in section, as that studied by Professor Angus in Fig. 11. At each of these discontinuities there is a loss of head due to kinetic energy losses, depending upon the sense and magnitude of the flow, and due directly to the change in character of the conduit. This loss may be evaluated[26] as $\left[1 - \left(\frac{d_1}{d_2}\right)^2\right]^2 \frac{V_1^2}{2\,g}$ in the case of an enlargement of section, and as $\left(\frac{1}{c} - 1\right)^2 \frac{V_2^2}{2\,g}$ in the case of a contraction. The effect of these losses, whether due to contraction or enlargement, is always the same in that the pressure indicated by the graphical method is not the true pressure at the point being studied for both sections of the conduit. It is the true pressure, plus or minus the kinetic energy correction, for one of the sections; for instance, in the case treated by Professor Angus, with flow from Points *D* to *A* (that is, from the reservoir to the gate), there is a change in pressure at Points *C* and *B* due to the change in section, which is not shown in Fig. 11. The true pressure may be found in the following manner: Consider Section *A B* of the conduit, with a change in régime introduced by the gate closure. Then, the pressure-velocity relations in Section *A B* at some time, *i*, later are shown by the régime points, A_i and B_i. In Section *B C* of the conduit, however, the true pressure at Point *B* is not that shown by Point B_i since the loss of kinetic energy due to the sudden contraction at Point *B* has been considered. Therefore, to find the true pressure at Point *B*, Section *B C*, add to the pressure shown by Point B_i the head lost in contraction. In Fig. 24 this may be accomplished by extending Point B_i vertically upward a distance equal to $\left(\frac{1}{c} - 1\right)^2 \frac{V_{AB}^2}{2\,g}$ times the pressure scale of the graph. Then the characteristic lines representing the pressure-velocity relations in Section B C should start, not from Point B_i but from the corrected Point B_i. The same correction is necessary for each change in section.

[26] "Fluid Mechanics," by R. A. Dodge and M. J. Thompson, McGraw-Hill Co., 1937.

As noted by Professor Angus, and as more fully discussed elsewhere,[27] these terms may usually be neglected. If they are neglected, however, it should be remembered (particularly in regard to the pressure conditions at intermediate points in the conduit) that the results are not exact. Admittedly, the error in the final result is often very small. It is obvious that as the velocity head term, $\frac{V^2}{2\,g}$, increases in ratio to the pressure head the error becomes larger.

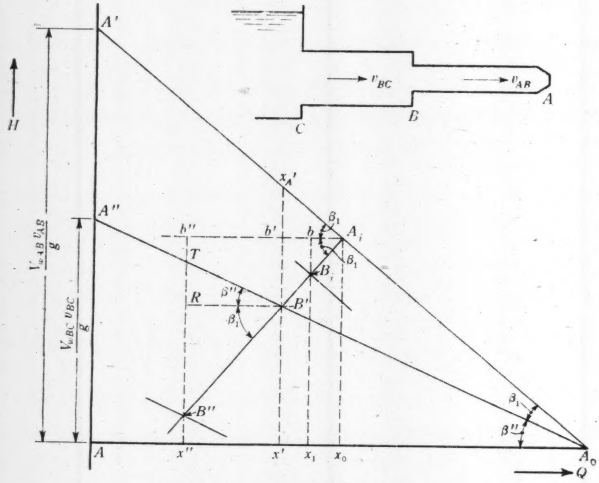

FIG. 24

In connection with corrections of this kind it should be noted that conditions frequently occur in practice which demand care in their interpretation as to the necessity for applying the foregoing corrections. Professor L. Bergeron has shown[27] that sometimes a correction need not be applied for flow in one sense, but for flow in the other sense a correction is required. For instance, he discusses the case of a nozzle opening into an air chamber, and the case of a simple pipe entrance. In the first case, the correction to be applied for reversed flow is four times that for normal flow; whereas, in the second case, no correction is required for flow in the normal sense (there being a negligible loss at the entrance); but, for flow in the reverse sense, correction must be made for the exit losses.

The study of water-hammer conditions in compound pipes by the graphical method offers a great advantage over the analytical method in that many of the factors that must be calculated in the latter method are automatically considered in the graphical method. Among these terms may be mentioned the so-called "coefficients" of reflection and transmission of the pressure waves, and in case the problem is being studied by the theory developed by Jaeger,[6] a third coefficient, α_i.

---

[27] Contributions to discussion of the papers by Messrs. L. Allievi, J. N. LeConte, and R. T. Knapp, at the Water Hammer Committee Meeting, A. S. M. E., 1937, by Prof. L. Bergeron and Martin A. Mason, Assoc. M. Am. Soc. C. E. (Publication pending.)

These terms may be easily found from the graphs drawn for a particular case, although their calculation is not at all necessary to the use of the graphical method. Fig. 24 is the graph for a simple case of a compound pipe consisting of two sections; the line, $A_0\,A'$, represents the pressure-velocity relation in Section $A\,B$, and Line $A_0\,A''$, the same relation as for Section $B\,C$. For simplicity, a pipe of only two sections has been chosen as the same proof applies equally well to compound pipes of any number of sections.

The construction of the graph by the graphical method shows the magnitude, F_i, of the direct pressure wave in Section $A\,B$, leaving End A at Time i, to be the length, $\overline{X_0\,A_i}$, in Fig. 24. Likewise, the magnitude of the reflected wave, f_i, from Point B, Section $A\,B$, is equal to the length, $\overline{-B'\,b'}$; and, the magnitude of the direct pressure wave, F', in Section $B\,C$, is equal to the length $\overline{X'\,B'}$, assuming that there are no reflected waves as yet in Section $B\,C$. Prolonging $X'\,B'$ to its intersection, X_A', with the line, $A_0\,A'$, $\overline{b'\,X_A'} = \overline{B'\,b'} = -f_i$; from which,

$$\overline{X'\,B'} = \overline{b\,X_1} - \overline{b'\,B'} = F_i - (-f_i) = F_i + f_i \quad\ldots\ldots\ldots(78a)$$

and,

$$\overline{X'\,X_A'} = \overline{b\,X_1} + \overline{b'\,X_A'} = F_i + (-f_i) = F_i - f_i \quad\ldots\ldots\ldots(78b)$$

Considering, however, the triangle, $A_0\,A'\,A''\,A$, cut by the parallel lines, $A\,A'$ and $X'\,X_A'$:

$$\frac{\overline{X'\,B'}}{\overline{X'\,X_A'}} = \frac{\overline{A\,A''}}{\overline{A\,A'}} = \frac{V_{wBC}\,v_{BC} \div \dfrac{1}{g}}{V_{wAB}\,v_{AB} \div \dfrac{1}{g}} = \frac{\dfrac{V_{wBC}}{A_{BC}}}{\dfrac{V_{wAB}}{A_{AB}}} \quad\ldots\ldots\ldots\ldots(79)$$

in which A represents the cross-sectional area of the conduit considered. Substituting the values of Equations (78) into Equation (79):

$$\frac{F_i + f_i}{F_i - f_i} = \frac{\dfrac{A_{AB}}{V_{wAB}}}{\dfrac{A_{BC}}{V_{wBC}}} = \frac{1 + \dfrac{f_i}{F_i}}{1 - \dfrac{f_i}{F_i}} \quad\ldots\ldots\ldots\ldots\ldots\ldots(80a)$$

and solving for $\dfrac{f_i}{F_i}$,

$$\frac{f_i}{F_i} = \frac{\dfrac{A_{AB}}{V_{wAB}} - \dfrac{A_{BC}}{V_{wBC}}}{\dfrac{A_{AB}}{V_{wAB}} + \dfrac{A_{BC}}{V_{wBC}}} = r \quad\ldots\ldots\ldots\ldots\ldots\ldots(80b)$$

which is recognized as the coefficient of reflection used by Jaeger, Loewy, Comte de Sparre, and others.

Furthermore, since $\overline{X' B'} = F' = \overline{X_1 b} - \overline{b' B'} = F_i + f_i$:

$$\frac{F'}{F_i} = 1 + \frac{f_i}{F_i} = \frac{\dfrac{2 A_{AB}}{V_{wAB}}}{\dfrac{A_{AB}}{V_{wAB}} + \dfrac{A_{BC}}{V_{wBC}}} = s \ldots\ldots\ldots\ldots\ldots (81)$$

which is the coefficient of transmission of Section *A B* into Section *B C*, applied in a manner similar to Equation (80*b*).

Consider, now, that there is a reflected wave, f', in Section *B C* (Fig. 24). For this case it is known by construction that Line $A_0 A''$ has been displaced parallel to itself a vertical distance equal to twice the magnitude of the reflected wave; that is, $2 f'$. Therefore,

$$\overline{B'' b''} = \overline{B'' R} + \overline{R b''} = \overline{B'' R} + \overline{B'' b'} = \overline{B'' R} - f_i \ldots\ldots (82a)$$

and since $\overline{B'' T} = - 2 f'$:

$$\overline{B'' R} + \overline{R T} = - 2 f' \ldots\ldots\ldots\ldots\ldots (82b)$$

From the similar triangles, *T R B'* and $A'' A A_0$, *B'' R B'* and $A' A A_0$, one finds,

$$\frac{\overline{R T}}{\overline{B'' R}} = \frac{\overline{A_0 A''}}{\overline{A_0 A'}} = \frac{\dfrac{A_{AB}}{V_{wAB}}}{\dfrac{A_{BC}}{V_{wBC}}} \ldots\ldots\ldots\ldots\ldots (83a)$$

and substituting Equation (83*a*) into Equation (82*b*):

$$\overline{B'' R} = - f' \left(\frac{2 \dfrac{A_{BC}}{V_{wBC}}}{\dfrac{A_{AB}}{V_{wAB}} + \dfrac{A_{BC}}{V_{wBC}}} \right) = - f' s' \ldots\ldots\ldots\ldots (83b)$$

in which s' is the coefficient of transmission of Section *B C* into Section *A B*.

To find Jaeger's coefficient, α_i, it is necessary only to consider Equations (83*b*) and (80*b*) with respect to Equation (82*a*), or,

$$\overline{B'' b''} = r F_i + s' f' \ldots\ldots\ldots\ldots\ldots (84a)$$

and, dividing by F_i,

$$\frac{\overline{B'' b''}}{F_i} = r + s' \frac{f'}{F_i} = \alpha_i \ldots\ldots\ldots\ldots\ldots (84b)$$

in which α_i, Jaeger's coefficient, represents the ratio of $\overline{B'' b''}$ (the reflected wave in Section *A B* due to reflection in Section *B C*) to the direct wave in Section *A B*.

Professor Bergeron, who with Dr. O. Schnyder, is mainly responsible for the rapid development of the graphical method of study of water-hammer phenomena, has shown[28] that the method may be applied successfully in fields other than that of hydraulics. In fact, theoretically, this method of study of pressure-velocity relationships may be adapted to any case in which the disturbing waves are propagated as plane waves. Thus, it can be used to study the propagation of plane waves in a stretched chord, longitudinal waves in a metal bar, torsional waves in a rotating cylinder, and the study of transients in electric lines.

---

[28] Mémoires de la Société des Ingénieurs Civils de France, *Bulletin*, July–August, 1937.

However, in many of these cases occurring in domains other than hydraulics (as well as in the field of hydraulics itself) difficulties are frequently introduced in the use of the method by the physical conditions under which the disturbance occurs. The principal of these difficulties is that of determining, at some time after the beginning of the disturbance, the characteristic curve of the pressure-velocity relations imposed by the disturbing device. In most cases this curve must be calculated by analytical means, as in the case of a surge tank consisting of an air reservoir, where, by means of Boyle's law, the pressure-velocity relations at any instant may be calculated. Unfortunately, this computation introduces, into the use of the graphical method for such cases, considerable additional work which it would be desirable to avoid. This phase of the problem of graphical solution of water-hammer problems is worthy of considerable study by those engineers who frequently use the graphical solution method.

A. A. KALINSKE,[29] ESQ. (by letter).—This paper, with previous writings by the author (which he lists in footnotes), provide, for American engineers, complete information on the solution of water-hammer problems by the graphical method. The writer suggests that any one wanting to become thoroughly familiar with this method of analysis should also consult the papers that are cited.

The presentation of a graphical method of analysis in a technical paper is extremely difficult as the author usually cannot get the reader to follow through, completely, the details of the graphical construction. Unless the reader does this, patiently and diligently, he will not grasp the principles of the graphical method. Furthermore, he is likely to use this method of analysis just as a tool, without any knowledge of the physical phenomena with which he is dealing.

The writer believes that the paper would be more lucid if Professor Angus had devoted additional space to showing what the graphical method of analysis really is; namely, a method for solving simultaneous equations. There is nothing mysterious about it; it is simply one method of solving, step by step, simultaneous equations that relate various phenomena which occur together. In fact, these simultaneous equations can be solved analytically just as well as graphically. Furthermore, only after solving a few problems analytically by a step-by-step numerical solution will the physical phenomena be entirely clear to any one who is just beginning the study of water-hammer. For example, when using the graphical method outlined by the author for compound pipes, the physical phenomena occurring at pipe junctions are completely obscured. The graphical method is a useful tool and is very convenient for some problems; it is unnecessary and cumbersome for certain others, and it is practically never indispensable. Some problems may be solved most rapidly by a combination of the numerical and graphical methods. An engineer interested in this problem should be able to use either method.

---

[29] Instructor in Hydraulics, and Research Engr., Coll. of Eng., State Univ. of Iowa, Iowa City, Iowa.

If an engineer knows how to write the different simultaneous equations that relate and control the various phenomena occurring in water-hammer, he will have no difficulty solving the problem. He may use a numerical or a graphical method, but, in either case, he should first have a correct understanding of what he is doing. The writer believes that Professor Angus might well have explained in more detail how to set up the various simultaneous equations needed to solve the more complicated piping problems, and thus have generalized the method of attack to be used in solving any particular problem.

In general, the solution of any water-hammer problem involves the formulation of the following: (1) Relation between the head and the velocity at the control gate; (2) relation between the head and velocity at one end of a section of uniform conduit, and the head and velocity at the other end of the same section taken an instant earlier than the first (this interval of time being equal to the time required for the pressure wave to travel the length of the conduit section); and, (3) discharge relationships at the junction of pipe branches.

As Professor Angus states, if friction loss is not neglected, the solution of any problem is considerably complicated. However, he minimizes the number of problems in which friction must be considered. In most water-supply pipe systems and pump discharge lines, the head lost due to friction is far from negligible. In many such problems the flow head may be only a small fraction of the static head. This fact is of great importance in the design of relief devices. By considering the friction loss as concentrated at a single point or points, an approximate solution can be obtained. However, such a procedure is far from satisfactory.

Probably the best physical pictures of the effect of friction on the form of the pressure wave for instantaneous closures are those given by W. F. Durand[30] and H. A. Gibson.[31] A complete, satisfactory explanation of the effect of friction for gradual gate closures does not seem to exist. In a paper published in 1937, Allievi[32] states:

> "During the perturbed regimen, moreover, the velocity of each single liquid filament is varying with time, and, at the same instant, is different for each filament. Therefore, the effect of liquid friction is transmitted to the lowest filament which we are considering, according to very complex laws in which it is legitimate to assume that the velocity, V_i, of the lowest identical filament plays a predominant part."

Probably the only way to obtain a correct idea as to the part that friction plays in altering the results obtained when it is neglected, or when it is considered as localized at various points, is through experiments. In fact, the writer believes that any further knowledge that is to be gained regarding water-hammer will have to be obtained from carefully conducted experiments. Mathematical and graphical analyses have solved most of the general features of the water-hammer problem; it is now time to investigate some of the minor assumptions that have been made. Some other special features of the problem, which merit experimental investigation, are the effects of sharp bends in pipes, gradual and sudden pipe transitions, partly closed valves, and the characteristics of various relief devices, including those that store up energy and those that dissipate it partly.

ROBERT W. ANGUS,[33] ESQ. (by letter).—The discussion by Professor DeJuhasz shows that the matter dealt with is of broad application. The writer agrees with the suggestion that the results become much clearer if represented by a solid instead of a plane diagram, and the elegant models made by Professor DeJuhasz[34] illustrate the meaning of the diagrams well. For problems met with in water-works and hydraulic systems, however, it is only necessary to determine the magnitude and location of the most dangerous pressure by the use of the diagrams shown.

It must be admitted that the method of dealing with friction is open to some criticism, but as the number of points of concentration of the friction is increased, the assumed pipe approaches the actual case more and more closely. If the number of points was infinite, the solution would be an exact one from the friction standpoint. Therefore, it becomes largely a question as to the number of points to concentration that must be used to avoid serious errors in the results, and judgment thus comes into the question. As the diagrams may be drawn very quickly, even the inexperienced person can try the same problem with one, two, three, or more, points of concentration, and in that way the minimum number is soon found; but the writer has observed that it is rarely necessary to assume more than two points, and very often one is sufficient.

In Fig. 20 the solution is offered for the case of two points of concentration where the resistance, $A_0 D_3$, is a little greater than 10% of the static head; but it would have been just as easy to solve the problem had $A_0 D_3$ been taken, say, at 95% of the static head, as would be the case in many water-works problems. Usually, sufficient accuracy is obtainable by assuming all the loss concentrated at the pipe entry and the corresponding diagram is easily deduced (see Fig. 25).[35]

Several of the discussers have dealt with friction, suggesting different ways of allowing for it, and some of these solutions may approach closer to the correct results than any yet suggested. There was no attempt in the paper to minimize the effect of friction, but it makes the diagrams more difficult to follow than if it were omitted; and the very small size of the diagrams suggested to the writer that it was best to omit it in most cases. The writer includes it in dealing with actual problems, and believes that, on the whole, the errors due to this phase of the work are much less than those due to uncertainties in the value of V_w and the exact effects caused by the turbine governor or other source of disturbance.

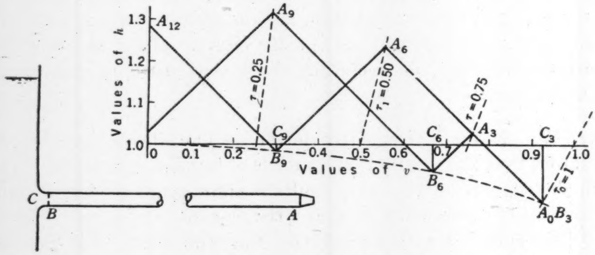

FIG. 25.—EFFECT OF FRICTION FOR STRAIGHT-LINE CLOSURE IN 12 SECONDS; $\rho' = 0.5$; $\frac{L}{V_w} = 3$ SECONDS

The analytical solution given by Professor Thomas is most instructive, and may also be derived from the writer's diagrams by writing down in succession the equations to the various lines on the diagrams. Since the slope of each line is known, and also its starting point, it is not difficult to solve for each point without the use of the drafting-board. The analytical solution forms a valuable check on the graphical one. There is more danger of error in the former than in the latter method, however, and it appears easier to detect mistakes on the diagrams than on the tabulated set of data. Mistakes may easily be made on the diagrams by drawing lines at the wrong slope, but once the correct slopes are established they are transferred very easily from place to place.

The writer has found that it is essential to be very careful with the slopes of the lines; otherwise they may become mixed when they are nearly parallel, and for this reason he used a separate diagram for each pipe, as in Fig. 14, etc., of the paper, in preference to the combined diagram, Fig. 23, shown by Professor Thomas. With the particular data of Fig. 23, that diagram is quite clear, but in many cases the lines become very much entangled and then the separate diagrams are best. The writer always puts all axes of v or V in the same horizontal line when working problems, so as to reduce the labor somewhat. Many geometrical shortcuts will suggest themselves, of which the one shown by Professor Thomas is ingenious. Scales must be arranged so that intersections are not too acute, and frequently it is desirable to use two vertical scales on the same drawing; in one case the writer found it convenient to use a scale for H of 10 ft = 1 in. up to H_0 = 100 ft, and 50 ft = 1 in. for values of H_0 greater than 100 ft; the engineer quickly adjusts himself to these solutions.

The points raised by Mr. Mason, Professor Danel, and Mr. Craya touch on several important matters. Undoubtedly, in principle, velocity head should be taken into account, as the writer has stated, and as is further emphasized by this discussion. It may be allowed for in various ways; thus, in Fig. 20, it has been treated similarly to friction by adding the velocity head to the friction loss, which has lengthened such lines as $B_3 B_3'$. In general, velocity head is relatively small and has very little influence. The modification shown in Fig. 24 is neat and ingenious and does not seriously lengthen the work.

Those who read the analytical method of computing water-hammer will appreciate the demonstration given by Messrs. Mason, Danel, and Craya of the derivation of the formulas for the transmission and reflection coefficients, which are difficult to understand and are well illustrated in the diagrams. The graphical construction includes them without appearing to do so. The derivation given shows the connection between the two methods of treatment and is a distinct addition to the literature on the subject.

The writer is pleased to find the desire, on the part of so many workers in the subject, to compare the analytical and the graphical methods. Jaeger[6] has been one of the exponents of the former method and Equation (84*b*) shows the connection of one of his important coefficients with the corresponding lines on the graphical diagram. Undoubtedly, the two methods must go side by side, recourse being had to parts of one and parts of the other where necessary; and the writer realizes that his own statement that in some cases analytical solutions were almost impossible, is capable of a much wider interpretation than was intended.

The three writers have called attention to a practical difficulty in solving water-hammer problems by any method due to the lack of exact knowledge of the pressure-velocity-time relations for the disturbing valve or gate; the solution cannot be more accurate than the data in this respect.

The discussion written by Mr. Knapp calls attention to the solution of the turbine and draft-tube problem illustrated by Fig. 17. Naturally, the turbine would vary somewhat in speed during gate closure and this would add to the disturbances entering the problem, but if all these features were discussed there would be ample material for a complete paper on that one problem. The writer was trying to illustrate the many different types of problems that could be solved, and Fig. 17 shows one in which he had been interested for some time.

The writer cannot conceive of a competent engineer deliberately designing a plant with the characteristics at Point D of Fig. 15, and then correcting it with a surge tank as in Fig. 16; nor has he suggested making the plant stable by means of the surge tank. Fig. 15 represents a type of plant that is common —that is, one in which a single supply pipe, $C\,B$, delivers water to two penstocks terminating in gates or nozzles used for turbines. In Fig. 15(*b*) the writer selected an arbitrary variation of h with v for the outlet at Point D and then investigated what happened. The inference from the investigation, clearly, is that such an arbitrary variation at Point D is incorrect; there may be other ways of determining this fact but the construction shown in the paper is a simple one.

The writer then added one more accessory to the plant by examining a surge tank located at Point B with the results shown in Fig. 16; but whether or not that is a desirable method has not been discussed. The tank certainly reduces the pressure swings and makes the system practicable "as far as the investigation has gone," and is "a further example of how these difficult problems may be solved simply and accurately, on the drafting board."

In regard to the derivation of Equations (10) the writer feels that he could scarcely have been expected to read the paper to which Mr. Knapp refers.[22] There are many methods of deriving these equations, the one adopted being sound and as reliable as any. This method appeals to some, but others may prefer a different one; and it makes little difference in the final outcome so long as there is confidence in the correctness of the equations.

The statements by Mr. Knapp that the writer worked "under assumptions that are fundamentally incorrect" and has obtained "results in accordance with these assumptions" is rather broad and, with a single qualification, to be discussed subsequently, is tantamount to a denial of Newton's Second Law. Before studying the paper in which Mr. Knapp calls "attention[18] to the incorrect solution of the problem under discussion," the reader would do well to analyze, carefully, the conditions imposed by the writer in solving the problem of Fig. 18 and the similar problem[21] reported by the writer in 1937. In referring to Fig. 18, the present paper states that "a vacuum valve is installed at Point *B* in such a manner as to prevent the pressure falling to that extent" (namely, below atmospheric pressure), and further, "the admission of air and its subsequent release at Point *B* maintains atmospheric pressure there until the columns re-unite." A similar statement is made for the 1937 paper to which Mr. Knapp refers[21] and in both cases it is assumed (although only stated in the latter), that Pipe *C B* rises somewhat in the vicinity of Point *B* so that the surface of the water must be horizontal while the columns are divided.

Under the first assumption, there could be no connection whatever between Columns *A B′* and *B″ C* from the time they part until they re-unite; and, both may be treated as distinct columns, as has been done, the air at Point *B* being always at atmospheric pressure. Mr. Knapp's first paper[18] refers to the case in which air is not admitted at Point *B* and where cavitation may occur with somewhat uncertain effects, in the present knowledge of this phenomenon. It is unfortunate that he has not given full details of his experiments[18] so that those interested might form an independent judgment on this subject.

The writer agrees with the criticism of the profile of Pipe *B C* which should be always at least 66 ft below Surface *C*. The actual case suggesting this problem was of a pipe where the total rise in Line *B C* occurred very close to the reservoir, in which case the solution is correct. It is only to this point that Mr. Knapp's sweeping criticism applies.

In his discussion, Mr. Kalinske thinks that the writer should have emphasized the fact that the method described is one for solving a set of simultaneous equations; but as Equations (23) and (26) make this quite clear, he had not thought it necessary to enlarge further on the fact. Instead of depending on an undue number of equations, a better grasp of the subject can be obtained from the broad variety of illustrations shown.

The writer agrees with Mr. Kalinske that with most engineers a clear conception of what happens in water-hammer is best obtained by first working a number of examples in a step-by-step process, and he uses this method with students as an introduction to the subject. He analyzed the "wave plan" described by R. Löwy,[36] and illustrated by Mr. Knapp,[13] but felt that it was not helpful enough to justify the time spent on it.

The writer expresses his thanks to all those who have been kind enough to contribute to this paper.

With Discussion by Messrs. K. Bert Hirashima, Merit P. White, and Lydik S. Jacobsen

Synopsis

An attempt has been made to give a quantitative answer to the question of the relative influence of different types of distortions on the natural periods of uniform cantilever beams elastically fixed at their bases. Very few buildings approximate the uniform and symmetrical beam dealt with in the theory, so that close agreement with actuality cannot be expected if the theory is applied to buildings. However, it is felt that the study enables the designer of earthquake resistant structures to put his finger on the most important factors entering into a determination of periods. The order or magnitude of errors committed by neglecting either flexure or shear in the building and by neglecting elastic yielding of the ground may be inferred from the tables, curves, and approximate formulas of the paper. Quantitative data relating to ground rigidities are as yet rather speculative, but it is hoped that the theory presented will help investigators to form reasonable estimates of the magnitudes of the ground rigidities from field data of natural vibrational periods of buildings.

Introduction

Transverse vibration frequencies of uniform beams have usually been computed from a consideration of the dynamic, flexural distortions. (The term "flexural distortion" refers to distortions produced by bending moments only.) When the beams are long and slender, experimental evidence is in fair agreement with the theoretical results, especially for the fundamental mode, but if higher modes are considered, or if the beams are relatively stubby, the deviations from the simple theory increase with the order of the mode. Retaining Lord Rayleigh's correction for the effect of rotatory inertia of the beams, S. Timoshenko[2] introduced a second correction for shear and solved the problem of

[2] "Vibration Problems in Engineering," by S. Timoshenko, 1928, p. 231.

frequencies for a uniformly loaded beam resting simply on rigid supports. In the case of a beam of rectangular cross-section, he found that the shear correction is four times larger than the one due to rotatory inertia. Using methods of successive approximations, V. I. Novotorzev[3] studied the effect of shear, rotatory inertia, and longitudinal elasticity on the fundamental frequency of beams and of simple bents. He found that for a rigidly built-in cantilever beam of rectangular cross-section, with a length to depth ratio of 4.56, the effect of shear distortion is to lower the frequency 3.3% from that obtained by considering flexural distortions alone, and that the combined effect of flexure, shear, and rotatory inertia amounted to a 4.2% lowering of the frequency. (The term, "shear distortion," refers to distortions produced by shear only.)

In regard to the higher mode frequencies the correction occasioned by shear will increase with the order of the mode until very soon a much better approximation of the frequencies results from a consideration of shear alone rather than from flexure alone. Quantitative data for the higher modes of cantilever beams, to the writer's knowledge, have not been previously published.

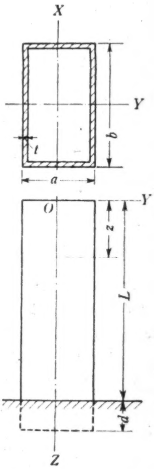

Fig. 1.—Co-Ordinate System and Dimensions

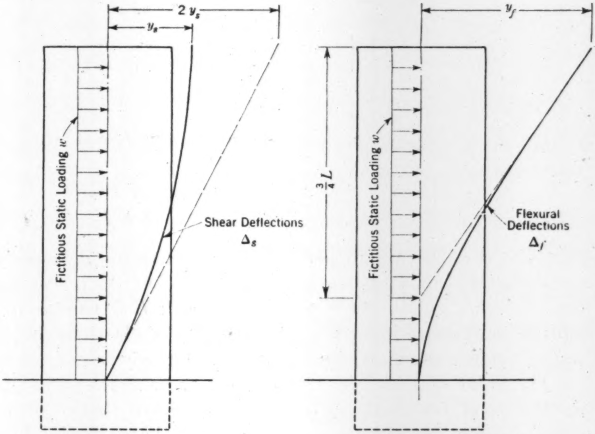

(a) DUE TO SHEAR

(b) DUE TO FLEXURE

Fig. 2.—Static Deflections of a Uniformly Loaded Cantilever

In vibration studies of beams it has been customary to assume simple end conditions as, for instance: (1) Entirely free; (2) rigid for translation and free for rotation; (3) rigid for rotation and free for translation; and (4) rigidly built-in. Frequency studies of cantilever beams with elastic constraints at the built-in end have undoubtedly been made for cases of flexure alone and shear alone,[4] but it is believed that the cantilever frequencies due to flexure, shear, translatory and rotatory elastic yielding of the built-in end have not been published before.

[4] *Zeitschrift für technische Physik*, No. 7, 1927, p. 269. (E. Schwerin considers elastic restraints at the end of a non-uniform beam subjected to flexure only.)

Consider a vertical, uniform cantilever beam of rectangular cross-section and of a free length L. The beam is "planted" to a depth, d, in an elastic medium (see Fig. 1).

Notation.—The symbols used in this paper are defined where they first appear and are assembled for reference in Appendix I.

STATIC DISTORTIONS OF THE BEAM ITSELF

Since the elastic properties of the cantilever beam have something to do with its vibrations, the first step is to examine some of the static distortions that would occur if a hypothetical, horizontal, uniform loading of the same intensity as the uniform weight of the beam were to act in the Y direction. The beam will then deflect horizontally so that shear deflections, Δ_s, and flexural deflections, Δ_f, become established as shown in Fig. 2. If the origin of the co-ordinate system is at the top of the beam and z is measured positive downward, the deflections of a cantilever beam with a rigidly built-in end are:

$$\Delta_s = \frac{Y_s\, w}{2\, A\, G} (L^2 - z^2) \quad \text{(1a)}$$

$$(\Delta_s)_{\max} = y_s = \frac{Y_s\, w\, L^2}{2\, A\, G} \quad \text{(1b)}$$

$$\Delta_f = \frac{w}{24\, E\, I_x} (3\, L^4 - 4\, L^3\, z + z^4) \quad \text{(1c)}$$

$$(\Delta_f)_{\max} = y_f = \frac{w\, L^4}{8\, E\, I_x} \quad \text{(1d)}$$

in which, w is the weight per unit height of beam, in pounds per inch; A is the cross-sectional area of beam, in square inches; I_x is the moment of inertia of beam section about the X-axis, in inches^4; E is the modulus of elasticity, in pounds per square inch; G is the modulus of elasticity in shear, in pounds per square inch; and, Y_s is the shear deflection coefficient, which is dimensionless.

The value of Y_s is generally not the same as the shearing stress distribution coefficient of 1.5 resulting from the simplified theory of a parabolic shearing stress distribution over the cross-section. According to Theodor von Kármán, M. Am. Soc. C. E., and F. Seewald[5] the influences of the non-linear distribution of longitudinal stresses as well as the transverse stresses due to the lateral deformation depend on the value of Poisson's ratio, $\frac{1}{m}$, and for a solid rectangular cross-section of a narrow width must be taken into account as follows:

$$Y_s = \frac{3}{2} - \frac{3\, m}{10\, (m + 1)} - \frac{3}{4\, (m + 1)} \quad \text{(2)}$$

The first member on the right-hand side of Equation (2) is the usual shear distribution coefficient first evaluated by Grasshof.[6] The second member gives the correction due to the longitudinal stresses, and the third represents the correction necessitated by the lateral deformation of the beam. Thus, if $\frac{1}{m}$ is one-third, $Y_s = 1.500 - 0.225 - 0.188 = 1.087$; and, if $\frac{1}{m}$ is one-fourth, $Y_s = 1.50 - 0.24 - 0.15 = 1.11$.

[6] "Der Stahlbau," by R. Gran Olsson, 1934, Vol. 2.

It should be mentioned that for any built-in beam, such as a cantilever, several possible but different assumptions relating to the type of distortional constraint, as amplified by warping of the cross-section at the built-in fixed end, lead to different expressions for the effect of shearing force on the deflection.[7]

If the cross-section of the beam is different from the rectangular (as, for instance, those shown in Fig. 3) the foregoing considerations in regard to the value of Y_s do not apply quantitatively, and the designer is forced to assign somewhat arbitrary values to the shear deflection coefficients. In view of the fact that deflection experiments on H-beams in the Y-direction, Fig. 3(*c*), are in fair agreement with the simple theory when Y_s is taken equal to the shearing stress distribution coefficient, this assumption may be accepted until better approximations become available. The simple static moment formula of elementary strength of materials, therefore, is used,

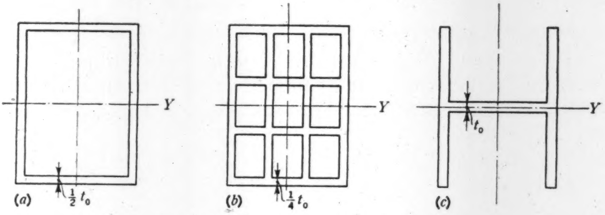

FIG. 3.—EXAMPLES OF CROSS-SECTIONS

$$Y_s = \frac{A \int_0^{a/2} y \, dA}{t_0 \, I_x} \quad \text{.....................} (3)$$

Example 1.—If t_0 (the thickness of the section at the neutral axis) is small in comparison with a and b, and if $a = b$, the value of Y_s for the box section is 2.25; for the cellular section, 2.58; and for the H-section, 3.11. These values are two to three times greater than for the rectangular solid cross-section; in other words, shear is of relatively great importance in a study of the sections shown in Fig. 3.

In addition to the fictitious horizontal loadings producing the lateral deflections in the Y and in the X-directions, the beam may be twisted about its vertical axis by a fictitious torsional twisting moment of $w\,k$ lb-in. per unit height. Under these circumstances the angle of twist will be given by:

$$\phi = \frac{w\,k}{2\,G\,R_t}(L^2 - z^2) \quad \text{.....................} (4a)$$

---

[7] "Theory of Elasticity," by S. Timoshenko, McGraw-Hill, 1934, pp. 37, 150.

and,

$$(\phi)_{\max} = \phi_R = \frac{w\,k\,L^2}{2\,G\,R_t} \qquad \text{(4b)}$$

in which k = radius of gyration of the cross-section, in inches; and $G\,R_t$ = torsional rigidity, in pound-inches^2. The value of R_t for the beam of rectangular cross-section is found from the St. Venant table printed in most textbooks.[8] If the cross-section of the beam is of the types shown in Fig. 3, R_t is best evaluated by use of the Prandtl membrane analogy, also found in textbooks.[8] However, if the box section or the cellular section has transverse horizontal diaphragms spaced at regular vertical intervals, as in the case of buildings with floors, the torsional shear distribution is influenced by these diaphragms, and somewhat arbitrary assumptions must be made in regard to the torsional properties of the beam. It is suggested that in this case R_t be defined as a summation of the products of the individual areas by the squares of their normal distances from the center of twist. For example, in the case of the rectangular box section of thickness, t,

$$R_t = \frac{1}{2}\,(a\,b^2 + a^2\,b)\,t \qquad \text{(5a)}$$

If the membrane analogy had been used:

$$R_t = 2\,\frac{a^2\,b^2}{a + b}\,t \qquad \text{(5b)}$$

Equations (5*a*) and (5*b*) give identical results when $b = a$, but when $b = 2\,a$, the first, and recommended, expression gives a value of 12% greater rigidity than the second. The arbitrary assumptions are especially necessary when sections of the cellular type are considered.

HYPOTHETICALLY ISOLATED VIBRATION FREQUENCIES OF A RIGIDLY BUILT-IN CANTILEVER BEAM

The transverse vibrations resulting from a consideration of shear alone are found from the well-known equation of motion:[9]

$$\frac{\partial^2 y}{\partial z^2} = \alpha^2\,\frac{\partial^2 y}{\partial t^2} \qquad \text{(6)}$$

in which $\alpha^2 = \dfrac{Y_s\,w}{g\,A\,G}$, giving the frequency equation:

$$\cos \alpha\,p\,L = 0 \qquad \text{(7)}$$

which means that the hypothetically isolated periods due to shear only may be expressed by:

---

[8] See, for instance, "Strength of Materials," by S. Timoshenko, Van Nostrand, 1930, Vol. I, p. 77, and Vol. II, p. 623.

[9] "Vibration Problems in Engineering," by S. Timoshenko, p. 216.

$$(T_s)_1 = 0.288 \sqrt{y_s} \quad \ldots\ldots (8a)$$

$$(T_s)_2 = \frac{1}{3} (T_s)_1 \quad \ldots\ldots (8b)$$

$$(T_s)_3 = \frac{1}{5} (T_s)_1 \quad \ldots\ldots (8c)$$

$$(T_s)_4 = \frac{1}{7} (T_s)_1 \quad \ldots\ldots (8d)$$

in which the maximum shear deflection, y_s, is given in inches. A consideration of flexural distortions only leads to the equally well-known equation of motion[10]:

$$\frac{\partial^4 y}{\partial z^4} = - \beta^2 \frac{\partial^2 y}{\partial t^2} \quad \ldots\ldots (9)$$

in which $\beta^2 = \frac{w}{g\, I_x\, E}$, giving a frequency equation:

$$\cos \sqrt{\beta\, p\, L^2} \cosh \sqrt{\beta\, p\, L^2} = - 1 \quad \ldots\ldots (10)$$

which means that the hypothetically isolated periods due to flexure only may be expressed by:

$$(T_f)_1 = 0.258 \sqrt{y_f} \quad \ldots\ldots (11a)$$

$$(T_f)_2 = \frac{1}{6.27} (T_f)_1 \quad \ldots\ldots (11b)$$

$$(T_f)_3 = \frac{1}{17.6} (T_f)_1 \quad \ldots\ldots (11c)$$

$$(T_f)_4 = \frac{1}{34.4} (T_f)_1 \quad \ldots\ldots (11d)$$

in which the maximum flexural deflection, y_f, is given in inches.

The torsional vibrations are not influenced by flexure since they involve shear or torsional distortions only. They may be obtained from Equations (6), (7), and (8), therefore, by replacing the coefficient, α, with α_ϕ, giving:

$$\frac{\partial^2 \phi}{\partial z^2} = \alpha_\phi{}^2 \frac{\partial^2 \phi}{\partial t^2} \quad \ldots\ldots (12)$$

in which $\alpha_\phi{}^2 = \frac{w\, k^2}{g\, R_t\, G}$, giving a frequency equation:

$$\cos \alpha_\phi\, p\, L = 0 \quad \ldots\ldots (13)$$

Therefore, the actual torsional periods are expressed as follows:

$$(T_R)_1 = 0.288 \sqrt{k\, \phi_R} \quad \ldots\ldots (14a)$$

$$(T_R)_2 = \frac{1}{3} (T_R)_1 \quad \ldots\ldots (14b)$$

$$(T_R)_3 = \frac{1}{5} (T_R)_1 \quad \ldots\ldots (14c)$$

---

[10] "Vibration Problems in Engineering," by S. Timoshenko, p. 222.

and,

$$(T_R)_4 = \frac{1}{7}(T_R)_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14d)$$

in which the maximum torsional angle at the top of the beam is ϕ_R.

TRANSVERSE PERIODS OF A RIGIDLY BUILT-IN CANTILEVER BEAM

Before considering the elastically yielding end fastening of the beam, it is interesting to inquire as to the extent to which flexural and shear distortions are of importance in a study of the transverse periods of the rigidly built-in beam. For very stubby beams Equations (6), (7), and (8) give good results, and for very slender beams Equations (9), (10), and (11) apply. If the beams are neither stubby nor slender, Equation (45*a*) of Appendix II must be used. Table 3(*a*) (Appendix II), gives solutions of this equation in the form of period ratios, $\frac{T}{T_s}$ and $\frac{T}{T_f}$, in terms of the flexure-shear ratio, $\mu = \frac{y_f}{y_s}$. Thus, if the maximum static deflections from Equations (1) of the fictitiously loaded beam are equal, the ratio, μ, is unity, and the true periods will be:

For the fundamental mode,

$$T_1 = (1.32)\ 0.288\ \sqrt{y_s}, \quad \text{or} \quad T_1 = (1.47)\ 0.258\ \sqrt{y_f};$$

for the second mode,

$$T_2 = (1.20)\ \frac{0.288}{3}\ \sqrt{y_s}, \quad \text{or} \quad T_2 = (2.80)\ \frac{0.258}{6.27}\ \sqrt{y_f};$$

and for the fourth-mode period,

$$T_4 = (1.03)\ \frac{0.288}{7}\ \sqrt{y_s}, \quad \text{or} \quad T_4 = (5.64)\ \frac{0.258}{34.4}\ \sqrt{y_f}.$$

A comparison of the ratios, $\frac{T}{T_s}$ and $\frac{T}{T_f}$, of Table 3(*a*) (Appendix II) for any specific value of μ and for a specific mode of vibration gives an idea of the relative importance of shearing and of the flexural distortions of the beam in regard to period calculations. Thus, for the fundamental mode of the beam with $\mu = 1$, the ratios, $\frac{T}{T_s} = 1.32$, and $\frac{T}{T_f} = 1.47$, signify that if flexure is neglected entirely and if only shear distortions are considered, the true period is 32% longer than the computed period. On the other hand, if shear is neglected the true period is 47% longer than the period resulting from a consideration of flexure only. Therefore, in this case, the error due to neglecting shear is greater than that resulting from a neglect of flexure. When $\mu = 1.25$, the errors in the period due to neglecting either shear or flexure are equal and amount to 40 per cent. For values of μ greater than 1.25 a better approximation of the fundamental period results from a consideration of flexure only than from one of shear only.

For the second-mode periods the errors due to neglecting either shear or flexure are not equal until the ratio, μ, is 5.4. At this value the errors are 56 per cent. In the third-mode and the fourth-mode periods equalities of errors for the two methods of computation do not occur within the limits of extrapolation of Table 3(a) (Appendix II). In general, one may conclude that for cantilever beams, rigidly built-in, a consideration of shearing distortions rather than one of flexural distortions is of importance for the higher modes of vibration unless the beam is very slender so that the ratio, μ, becomes large.

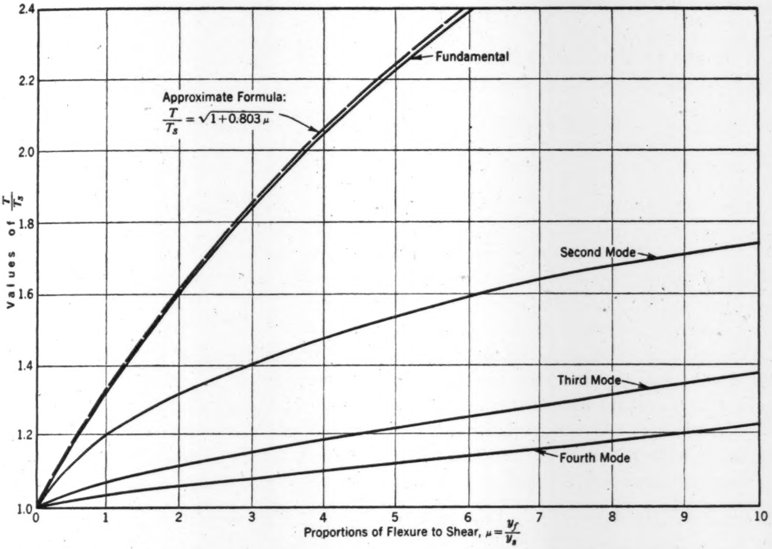

FIG. 4.—GENERAL CURVES FOR FIRST FOUR TRANSVERSE MODE PERIODS OF UNIFORM CANTILEVER BEAMS SUBJECTED TO DYNAMIC SHEAR AS WELL AS TO DYNAMIC FLEXURE; RIGID GROUND

In order to emphasize the significance of Table 3(a) (Appendix II), Fig. 4 and Tables 3(b), 3(c), and 3(d) have been included. Table 3(b) (Appendix II) refers to a cantilever beam with a solid square cross-section. The shear deflection coefficient, Y_s, is taken equal to 1.2, and the modulus of elasticity, E, is taken equal to 2.5 G. In this case equalities of errors in period of the fundamental mode occur when the height-to-depth ratio, $\frac{L}{a}$, is 1.1; for the second mode when $\frac{L}{a}$ is 2.3; for the third mode when $\frac{L}{a}$ is 3.9; and for the fourth mode when $\frac{L}{a}$ is 5.3. This means that in most beams of solid square cross-section, only relatively stubby ones require that both types of distortions be considered for computations of periods. Shear distortions may be neglected except for the higher modes of vibration.

It is interesting to note that for $\frac{L}{a} = 4$, Ratio $\frac{T}{T_f}$ is 1.04, which means that the lengthening of the period due to shear is 4 per cent. This is in good agreement with the result obtained by Novotorzev[3] of 3.3% for a beam with $\frac{L}{a} = 4.56$.

In 1894, S. Dunkerley[11] showed that the resultant period, T_r, of a complicated system may be expressed empirically to a fair degree of approximation in terms of the "isolated component" periods, T_a, T_b, $\cdots$ T_n, as follows:

$$T_r^2 = T_a^2 + T_b^2 + \cdots T_n^2 \ldots\ldots\ldots\ldots\ldots\ldots \quad (15)$$

In the present case, in which the two "isolated component" periods are the one due to shear alone, and the one due to flexure alone,

$$T_{sf}^2 = T_s^2 + T_f^2 = 0.288^2\, y_s + 0.258^2\, y_f \ldots\ldots\ldots\ldots \quad (16)$$

and,

$$\frac{T_{sf}}{T_s} = \sqrt{1 + 0.803\,\frac{y_f}{y_s}} = \sqrt{1 + 0.803\,\mu} \ldots\ldots\ldots\ldots \quad (17)$$

The empirical formula, Equation (17), is in good agreement with the exact theory as may be seen from the dotted curve on Fig. 4. In this case the error is positive, but in other cases it may be either positive or negative (see Fig. 6, for instance). However, it should be emphasized that the approximate formula does not have the slightest application to the period ratios of the higher modes, and that it is precisely for these modes that considerations of flexure alone give erroneous results unless the beams are very slender indeed.

Table 3(*c*) (Appendix II) relates to a cantilever beam of a square box cross-section with Y_s equal to 2.25 and with E equal to 2.5 G. In this case equality of errors in periods for computations involving shear alone and flexure alone occurs for the fundamental mode when $\frac{L}{a}$ is 2.2; for the second mode when $\frac{L}{a}$ is 4.5; and for the third mode when $\frac{L}{a}$ is 7.6. Table 3(*c*) does not extend far enough to give this ratio for the fourth mode. It is seen that in the case of the cantilever beam with a square box cross-section shearing as well as flexural distortions must be considered even if the values of $\frac{L}{a}$ are appreciable.

The period ratios for the beam with the rectangular box cross-section of a width-to-depth ratio of 3.1 are given in Table 3(*d*) (Appendix II). In this case Y_s is 4.45 so that a relatively large shear effect is present. From Table 3(*d*) it is found that equalities of errors in periods for the two types of distortion occur when $\frac{L}{a}$ is 3.4 for the fundamental mode, when $\frac{L}{a}$ is 7.2 for the second mode, and when $\frac{L}{a}$ is between 12 and 13 for the third mode.

If the beam with rectangular box cross-section is considered to be somewhat akin to a very much idealized building, it is clear that the influence of shearing distortions on its natural periods is far from negligible; indeed, for buildings of ordinary proportions a consideration of shear alone will give better approximations of the true natural periods, including the second mode and those above it, than a consideration of flexure alone. Of course, for the fundamental-mode period both types of distortion are of importance.

---

[11] *Philosophical Transactions*, Royal Soc., Lond., Vol. 185 (1894), p. 311.

RATIOS OF NATURAL PERIODS

Table 3(*d*) (Appendix II) also gives the ratios of the true fundamental periods to the true higher mode periods for the rigidly built-in cantilever beam with rectangular box cross-section of $\frac{b}{a} = 3.1$. The ratios of 3, 5, and 7 for the case of shear alone (Equations (8)) are obtained when $\frac{L}{a}$ approaches zero, and the ratios of 6.27, 17.6, and 34.4 for the case of flexure alone are theoretically approached as $\frac{L}{a}$ becomes infinite. When $\frac{L}{a}$ is 10—a very large ratio for a building—the period ratios, 5.28, 11.1, and 17.5, are quite far from either of the two sets of limiting ratios. Finally, it may be concluded that even in the case of a rigidly built-in, uniformly loaded, cantilever beam the ratios of natural periods are not very simple.

END CONSTRAINTS OF THE CANTILEVER BEAM

In proceeding to a study of the effect, on the periods, of the elastic constraint at the built-in end, it will be assumed that the medium in which the cantilever beam is "planted" is capable of exerting elastic restoring forces and moments on the end of the beam. The inertia of the medium is neglected and, for the time being, the restoring force properties of the medium and "planting" may be thought of as resulting from static experiments. Appendix III includes a description of a crude, rational method of relating the restoring properties of the ground and "planting" to ground deformation moduli.

The translatory rigidities offered by the ground to the "planted" beam in the X-direction and in the Y-direction are defined by R_x and R_y. The units are pounds per inch of translation. If the fictitious horizontal loading of the weight, $w\,L$, of the beam itself is assumed to act in the Y-direction, the corresponding horizontal translation of the base of the beam in this direction, in inches, is given by:

$$y_t = \frac{w\,L}{R_y} \dots\dots\dots\dots (18)$$

In regard to the rotatory or tilting rigidity of the ground, it is assumed that the horizontal axis about which rotation or tilting occurs lies in the plane of the surface of the ground. The rotatory restraints of the ground upon the beam about the X- and Y-axes in the plane of the ground are then given by $R_{x\theta}$ and $R_{y\theta}$. The units are pound-inches per radian. If the fictitious horizontal loading of the weight of the beam itself, $w\,L$, is assumed to act in the Y-direction, the vertical axis of the beam will be inclined in the $Z\,Y$ plane and the maximum linear displacement at the top of the beam, in inches, will be given by,

$$y_r = \frac{w\,L^3}{2\,R_{y\theta}} \dots\dots\dots\dots (19)$$

The fifth rigidity of the ground relates to the torsional constraint of the ground acting through the "planted" part of the beam. It will be assumed again that this rigidity is measured about the vertical axis of the beam in the plane of the ground. It is denoted by R_ϕ and its dimensions are pound-inches per radian. The effect of the fictitious torsional moment of $w\,L\,k$ lb-in. about the vertical axis of the beam will be an angle of rotation of the base of the beam, in radians, with respect to the ground of the magnitude,

$$\phi_g = \frac{w\,L\,k}{R_\phi} \quad \text{(20)}$$

It is important to note that in the case of a homogeneous elastic ground the five rigidities, R_x, R_y, $R_{x\theta}$, $R_{y\theta}$, and R_ϕ are functions of the properties of the ground as well as of the dimensions, a, b, and d of the "planting."

Influence of the Ground on the Torsional Periods

Since flexure in the building as a whole does not affect its torsional properties, the torsional-mode periods of the elastically built-in cantilever beam can be found from a general solution of Equation (47a), of Appendix II, if the shear coefficients, α and τ, are replaced by the torsional coefficients, α_ϕ (in radians per inch per second) and $\tau\phi$ (in second^2 per inch per radian), defined as follows:

$$\alpha_\phi = \sqrt{\frac{w\,k^2}{g\,R_t\,G}} = \sqrt{\frac{2\,k\,\phi_R}{g\,L^2}} = 0.072\sqrt{\frac{k\,\phi_R}{L^2}} \quad \text{(21a)}$$

and,

$$\tau_\phi = \frac{w\,k^2}{g\,R_\phi} = \frac{k\,\phi_g}{g\,L} \quad \text{(21b)}$$

With these substitutions, Equation (47a) (Appendix II) may be written thus:

$$\frac{0.454\,\sqrt{k\,\phi_R}}{T}\tan\left(\frac{0.454\,\sqrt{k\,\phi_R}}{T}\right) = 2\,\frac{\phi_R}{\phi_g} \quad \text{(22)}$$

Solutions of this transcendental equation yield the torsional periods for any cantilever beam with elastic, torsional constraint at the built-in end for assumed values of the torsional rigidity ratio, $\psi = \frac{\phi_g}{\phi_R}$. The torsional periods of the nth mode of vibration are expressed by,

$$T_n = \left(\frac{T_{Rg}}{T_R}\right)_n \frac{0.288}{2\,n - 1}\,\sqrt{k\,\phi_R} \quad \text{(23)}$$

Fig. 5 shows the values of the period ratios that must be used in Equation (23). Furthermore, it shows that as elastic torsional yielding of the ground increases, the fundamental torsional period becomes longer and longer, so that the second-mode torsional period approaches the fundamental mode torsional period for the beam with both ends free; similarly, the third-mode period approaches the second-mode period for the free beam, etc. The ratios of the fundamental torsional periods to those of the higher modes are close to the values 3, 5, 7, and 9 for small values of the ratio, ψ.

If Dunkerley's empirical formula (see Equation (15)) is applied to the fundamental mode of torsion,

$$T_{Rg} = \sqrt{T_R^2 + T_g^2} = \sqrt{(0.0830\,\phi_R + 0.1024\,\phi_g)\,k} \quad\ldots\ldots(24)$$

and,

$$\frac{T_{Rg}}{T_R} = \sqrt{1 + 1.23\,\frac{\phi_g}{\phi_R}} = \sqrt{1 + 1.23\,\psi} \quad\ldots\ldots(25)$$

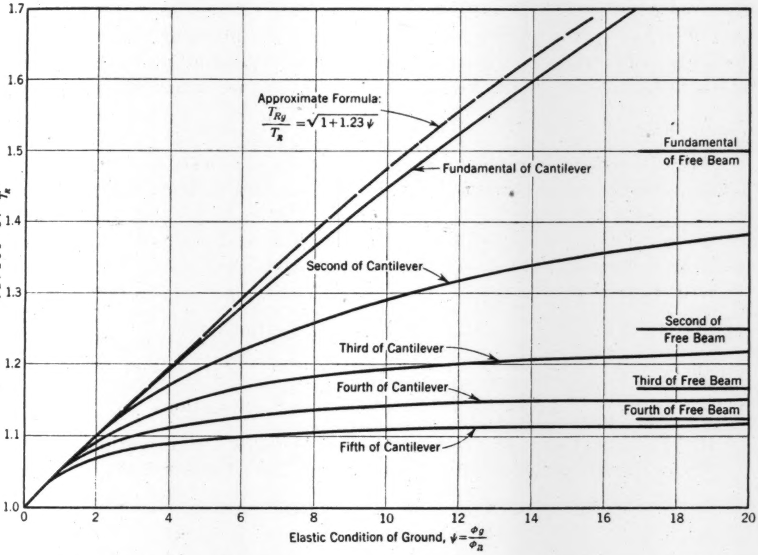

FIG. 5.—GENERAL CURVES FOR FIRST FIVE TORSIONAL MODE PERIODS OF UNIFORM CANTILEVER BEAMS "PLANTED" IN A TORSIONALLY ELASTIC GROUND

The results of Equation (25) are plotted on Fig. 5 as a broken-line curve. It is suggested that the approximate formula is accurate enough for practical purposes.

INFLUENCE OF THE GROUND ON THE PERIODS OF THE TRANSVERSE VIBRATIONS

In Appendix II the general problem of the free vibration periods of cantilever beams has been solved by considering shear and flexure of the beams as well as translatory and rotatory elastic yielding of the ground. Since the writer's primary interest in the application of the results centers on idealized buildings, a specific but fictitious building has been chosen to illustrate the significance of the theoretical deductions in Appendix II.

Example 2.—A cantilever beam of rectangular box cross-section, Fig. 3(*a*), is defined as follows: (1) Period due to shear alone, 1 sec = $(T_s)_1$; (2) height, 200 ft, or 2 400 in. = L; (3) depth, 52.5 ft, or 630 in. = a; (4) width, 170.0 ft, or 2 040 in. = b; (5) radius of gyration, 35 ft, or 420 in. = k; and (6) depth of "planting," 20 ft, or 240 in. = d.

The ground in which the cantilever beam is planted is defined by: (7) Horizontal deformation modulus, ϵ_h, and shear deformation modulus, ϵ_s, are equal (see Appendix III); and, (8) vertical deformation modulus, ϵ_v, is twenty-five times larger than ϵ_h; or $\frac{\epsilon_v}{\epsilon_h} = \gamma = 25$.

The yielding of the ground in translation, in rotation, and in shear may then be expressed, according to Appendix III, by the ground constants, ϵ_h and γ, taken in the proper combination with the physical dimensions of the building. The ratio of the translatory ground deflection, y_t, to the maximum shear deflection, y_s, of the beam is then sufficient for characterizing uniquely the yielding of the ground. This ratio is called ν $\left(\text{that is, } \nu = \frac{y_t}{y_s}\right)$.

The discussion of the chosen example is confined to a study of the transverse translatory vibration periods in the Y-direction and to the torsional vibration periods about the Z-axis.

By considering the specifications of the beam and some of the given equations it is found that: $y_s = 12.1$ in. (Equation (8a)); $Y_{sx} = 4.45$ and $Y_{sy} = 1.70$ (Equation (3)); $A = 2\,(a + b)\,t = 5\,340\,t$ sq in.; $I_x = (\frac{1}{2}\,a^2\,b + \frac{1}{6}\,a^3)\,t = 444 \times 10^6\,t$ in.^{4}; $\frac{w}{G} = 5.04 \times 10^{-3}\,t$ in. (Equation (1b)); $\frac{w}{E} = 2.02 \times 10^{-3}\,t$ in. (if $E = 2.5\,G$); $y_f = 18.6$ in. (Equation (1d)); $(T_f)_1 = 1.11$ sec (Equation (11a)); $\mu = \frac{y_f}{y_s} = 1.54$; $R_t = 1.71 \times 10^9\,t$ in.^{4} (Equations (5)); $\phi_R = 3.57 \times 10^{-3}$ radians (Equation (4b)); and, $(T_R)_1 = 0.353$ sec (Equation (14a)).

From the specifications of the ground and from Equation (53a) (Appendix III): $\frac{y_t}{y_s} = \nu$ (different values of ν to be assumed); $\frac{y_r}{y_t} = \frac{(12\,d + 6\,b)\,L^2}{\gamma\,a^3 + 8\,d^3} = 13.8$; $\lambda = \frac{y_r}{y_s} = \frac{y_r}{y_t}\,\frac{y_t}{y_s} = 13.8\,\nu$; and, $\psi = 3.86\,\nu$ from Equation (54) (Appendix III).

Torsional Periods in Example 2.—The torsional coefficients, $\frac{T_{R0}}{T_R}$, of Equation (23) are easily found from Fig. 5 for the values of ψ corresponding to the assumed values of ν. From the results, as given in Table 1, it is seen that the fundamental torsional period increases indefinitely as ν increases. This means that a cantilever loses its fundamental mode as ν approaches infinity, or as its constraint at the built-in end approaches zero. The second-mode period of the motion of the cantilever with built-in end changes into the fundamental-mode period of the beam with free ends as ν approaches infinity. The third-mode period becomes the second-mode period, etc.

Transverse Periods in Example 2.—The solution of the frequency Equation (44) from Appendix III for the structure described by the foregoing constants and for assumed values of the ratio, ν, is a long and laborious task. The results are plotted in Figs. 6, 7, and 8.

TABLE 1.—TORSIONAL PERIODS, IN SECONDS, FOR THE FIRST FIVE MODES OF VIBRATION OF THE CANTILEVER BEAM REPRESENTING THE IDEALIZED BUILDING CHOSEN AS AN ILLUSTRATIVE EXAMPLE OF THE THEORY
(The Elastic Condition of the End Fastening Is Measured Either by ν or by ψ. The Ratios of the Fundamental to the Higher Mode Periods Are Also Given.)

Referring to Table 2(*a*), Item No. 1 gives the transverse periods of the structure on a rigid ground, computed on the assumption that shear alone governs the periods; thus, for instance, the fourth-mode period becomes one-seventh of the fundamental period, or 0.143 sec. The periods recorded as Item No. 2 involve the assumption that flexure alone governs the vibration. Item No. 3, still relating to the condition of a rigid ground, gives the so-called true periods of the structure. Items Nos. 4 to 12, inclusive, give true periods of the structure on a yielding ground; the degree of yielding is expressed by the value of ν. Item No. 13, for $\nu = \infty$ (that is, for a beam free at both ends), is a limiting case, and, consequently, when applied to a building is a physical impossibility. Its value lies in the fact that it indicates how closely the results for $\nu = 2$ approach those for $\nu = \infty$. It should be noted that for the higher mode periods the agreement between Items Nos. 12 and 13 is fairly close. The fundamental-mode period, however, increases without limit, which means that instability of motion results. Item No. 14 gives the periods of the structure with both ends free, computed from shear distortions only, whereas Item No. 15 gives the periods resulting from considering flexure alone. The third column of Table 2(*a*), relating to the fundamental period, has been plotted in Fig. 6.

TABLE 2.—PERIODS AND PERIOD RATIOS FOR THE FIRST SIX MODES OF TRANSVERSE VIBRATION OF THE CANTILEVER BEAM REPRESENTING THE IDEALIZED BUILDING CHOSEN AS AN ILLUSTRATIVE EXAMPLE OF THE THEORY

Item No.[*]	Values of the ratio, ν	(*a*) PERIODS, IN SECONDS, FOR THE FOLLOWING MODES:						(*b*) PERIOD RATIOS

[*] With the exceptions noted, the types of distortion are those due to shear, flexure, translation, and rotation, combined.

[†] Shear distortion only.

[‡] Flexure distortion only.

[§] Shear distortion and flexure distortion.

[¶] The elastic condition of the ground; the elastic condition of the end fastening is measured by the ratio, ν.

[**] In these items the numerator of the ratio is T_2 instead of T_1.

If Dunkerley's empirical formula (Equation (15)) is applied to the fundamental-mode period of the cantilever:

$$T_{sftr}^2 = 0.0830\, y_s + 0.0666\, y_f + 0.1024\, y_t + 0.0681\, y_r \ldots\ldots (26)$$

For the specific cantilever under consideration, in which: $\frac{y_f}{y_s} = 1.54$; $\frac{y_r}{y_s} = 13.8$; and, $\frac{y_t}{y_s} = \nu$: $T_{sftr}^2 = (1.855 + 1.042\, \nu)\, y_s$: and,

$$\frac{T_{sftr}}{T_s} = \sqrt{2.24 + 12.55\, \nu} \ldots\ldots\ldots\ldots\ldots\ldots (27)$$

The results of this empirical formula are given by the dotted curve on Fig. 6. It is seen that the error is negative in this case. However, it is suggested that for practical problems the Dunkerley formula, as expressed in the general form by Equations (8), is satisfactory.

Fig. 7 shows a plot of the higher mode periods as functions of ν, the yielding of the ground. The dotted, straight horizontal lines on the left and on the right of the individual graphs relate to the periods for zero and for infinite yielding of the ground. The second-mode period increases rather rapidly for a small yielding of the ground, reaches a maximum when ν is about 0.2, and then decreases along a smooth curve. When ν is 0.6 the period of the mode is the same as for the second mode with $\nu = 0$. As ν increases further, the period drops, and as ν approaches infinity the period approaches asymptotically the fundamental-mode period of 0.320 sec for the beam or structure with both ends free. A similar variation in period resulting from a yielding of the ground occurs for all the higher mode vibrations.

It has now been shown that the fundamental-mode period of the cantilever increases indefinitely as the yielding of the ground is increased; moreover, that the second-mode period of the cantilever on a rigid ground transforms into the fundamental-mode period of the beam with free ends as ν increases. The gradual transformations from the second mode to the fundamental, from the third to the second, from the fourth to the third, etc., are shown in Fig. 7. It is to be noted that the higher the mode, the smaller the value of ν necessary for bringing about the transformation.

On Fig. 8, the ratios of the fundamental to the higher mode periods are plotted as functions of ν. It is seen that these ratios are far from simple; in general, they increase with the yielding of the ground. If the curve for $\frac{T_1}{T_2}$ is considered, it is seen that the ratio of 6.3, due to flexure alone and for a rigid ground, really corresponds to a yielding ground of which the coefficient, ν, is more than 0.4. On the other hand, the ratio of 3 due to shear alone does not exist, since the curve for $\frac{T_1}{T_2}$ starts at 3.4 for a rigid ground.

The practical value of the tendencies indicated by these curves may be twofold: First, from observations of periods on existing buildings (the United States Coast and Geodetic Survey has done much observational work in California) the ground factors may be estimated. These factors must then be related to the geologic characteristics of the ground as well as to soil tests of foundation mechanics. Second, if enough types of cases have been studied, it becomes possible to predetermine the periods of proposed buildings with a fair degree of accuracy.

It will undoubtedly be realized that the significance of such analyses is not restricted to the somewhat narrow, as well as hypothetical, value of periods for purposes of aseismic design. The periods of the building proper are indices of its mass and elastic properties, but they cannot be evaluated correctly until the ground effect on the periods becomes separable. Finally, from the point of view of foundation mechanics the periods of existing buildings, when analyzed, will give information about the ground itself.

APPLICATIONS OF THE THEORY

The theory applies to any symmetrical cantilever beam provided that its weight per unit height, its shearing rigidity, and its flexural rigidity are constant. Whether or not the ground rigidities are given by the equations of Appendix II makes no difference as far as the application of the theory is

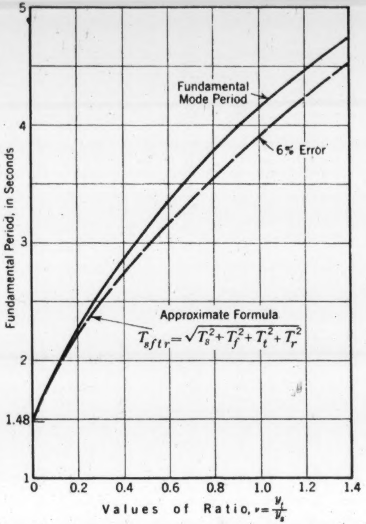

FIG. 6.—EFFECT OF AN ELASTICALLY YIELDING GROUND ON FUNDAMENTAL TRANSVERSE MODE PERIOD OF SPECIFIC CANTILEVER BEAM SUBJECTED TO SHEAR, FLEXURE, GROUND TRANSLATIONAL YIELDING AND GROUND ROTATIONAL YIELDING

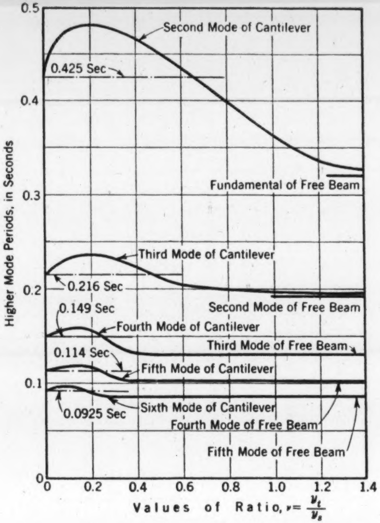

FIG. 7.—EFFECT OF ELASTIC GROUND ON HIGHER TRANSVERSE MODE PERIODS OF THE SPECIFIC CANTILEVER SUBJECTED TO THE FOUR TYPES OF YIELDING

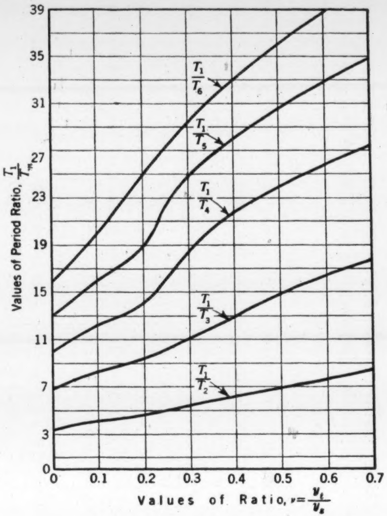

FIG. 8.—RATIOS OF FUNDAMENTAL TRANSVERSE MODE PERIOD TO HIGHER TRANSVERSE MODE PERIODS OF SPECIFIC CANTILEVER BEAM AS FUNCTIONS OF GROUND YIELDING

concerned. The necessary and sufficient condition for the ground is that its behavior must be elastic and symmetrical so that the ground coefficients, τ and ζ, Appendix II, can be evaluated.

In regard to buildings the theory will not apply with a satisfactory degree of quantitative accuracy on account of the fact that actual buildings, with a few exceptions, are far from satisfying the demands of constancy of mass and elastic properties with height; neither do they satisfy the condition of symmetry. It is thought, however, that qualitatively the theory explains the seemingly erratic data obtained from wind vibration records, or from shaking-machine vibration records of buildings. The theory indicates that for most buildings shear as well as flexure must be considered, and that the elastic yielding of the ground will influence the periods greatly.

If the data from period tests of actual symmetrical buildings are to be analyzed correctly, it becomes necessary to use graphical or mechanical methods for finding the component deflections due to shear, flexure, translatory, and rotatory rigidities of the ground.

A rough indication of the relative importance of the four factors influencing the periods of buildings may be obtained statistically from the observed data of the U. S. Coast and Geodetic Survey. The most important part of such an analysis is to choose carefully from the mass of data (about 200 to 300 buildings) the ones that satisfy most nearly the demands of twofold symmetry as well as isolation from other structures. Such a selection of data is found to decimate the number of buildings available.

Since it is known that the Dunkerley formula gives sufficiently accurate results for the fundamental-mode periods of uniform bars, and since, in the case of actual buildings, it may be supposed to apply, at least dimensionally, one may write:

$$T_{sftr} = \sqrt{c_1\,l + c_2\,l^2 + c_3\,l^3 + c_4\,l^4} \ldots\ldots\ldots\ldots\ldots (28)$$

in which l is a characteristic length-to-depth ratio of a building $\left(\text{that is, } \frac{L}{a} \text{ or } \frac{L}{b}\right)$, and the coefficients, c_1, c_2, c_3, and c_4, are to be determined from the available data. Thus, if four transverse fundamental periods of, say, two buildings of four different values of λ are known, four items of experimental information are available and may then determine uniquely the four coefficients. The significance of the four terms may then be explained as the component periods due to: Elastic ground translation, $\sqrt{c_1\,l}$; shear in the building, $\sqrt{c_2\,l^2}$; elastic ground tilting, $\sqrt{c_3\,l^3}$; and flexure in the building, $\sqrt{c_4\,l^4}$.

Of course, if more than four independent observations are available from which to find the four coefficients, the information will be redundant, and the method of least squares suggests itself for a statistical determination of the four coefficients.

GRAPHICAL AND MECHANICAL METHOD OF COMPUTING THE PERIODS

In its simplest form the problem of finding the period of one of the natural modes of vibration of an elastic system may be stated as the problem of finding a dynamic loading curve that will produce a geometrically similar, dynamic deflection curve. Although the two curves refer to dynamic conditions, they may be thought of as being static, so that a system subjected to an assumed dynamic loading curve may be treated by the well-known methods of statics in order to find its component deflections due to shear, flexure, and elastic ground yielding. The methods in question may be purely graphical, or graphical and numerical, or they may be a combination of static experimentation upon a mechanical system made up to represent the elastic properties of the system in shear, in flexure, and in end-fastening rigidity. It is possible, by means of simple strips, to build a static, elastic model of a building. The problem of finding the dynamic (that is, really, the static) loading curve that will produce an elastic deflection curve geometrically similar to the loading curve is merely a matter of sufficient experimentation by trial and error.

APPENDIX I

NOTATION

The following notation conforms essentially with American Standard Symbols for Mechanics, Structural Engineering and Testing Materials[12] compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

x = horizontal co-ordinate;
y = horizontal co-ordinate; direction of transverse vibration;
z = vertical co-ordinate, origin at top of beam;
b = dimension of beam in horizontal direction;
a = dimension of beam in horizontal direction; direction of vibration;
L = dimension of beam in vertical direction;
A = cross-sectional area of beam;
Y_s = shear deflection coefficient for Y-direction;
I_x = moment of inertia of cross-section for vibrational direction;
w = weight per unit height of beam;
g = acceleration due to gravity;
E = modulus of elasticity for bending;
G = modulus of elasticity for shear;
m = Poisson's number;
k = radius of gyration of cross-section;
$G R_t$ = torsional rigidity of beam about vertical axis;
Δ_s = shear deflection due to fictitious gravity load in horizontal direction;
Δ_f = flexural deflection due to fictitious gravity load in horizontal direction;
ϕ = torsional angle due to fictitious moment, $w\,k$, per unit height;
y_s = shear deflection at top of beam; horizontal gravity loading;
y_f = flexural deflection at top of beam; horizontal gravity loading;

---

[12] A.S.A.—*Z* 10*a*—1932.

μ = ratio, $\frac{y_f}{y_s}$;
ϕ_R = torsional angle at top of beam due to moment, $w\,k$, per unit height;
t = time in derivative notation; also, thickness of cellular sections;
t_0 = thickness of cross-section at neutral axis;
l = characteristic length ratio of beam or building;
c = coefficient;
d = depth of "planting" or embedment of beam in ground;
R_x = translatory rigidity of ground in X-direction;
R_y = translatory rigidity of ground in Y-direction;
$R_{x\theta}$ = rotatory or tilting rigidity of ground in $x\,z$-plane;
$R_{y\theta}$ = rotatory or tilting rigidity of ground in $y\,z$-plane;
R_g = torsional rigidity of ground for twist of beam about vertical axis;
y_t and x_t = displacements of top of building due to ground translational yielding;
y_r and x_r = displacements of top of building due to ground rotational yielding;
ϕ_g = angle of twist due to torsional yielding of the ground;
ϵ_v = deformation modulus of ground in vertical direction;
ϵ_h = deformation modulus of ground in horizontal direction;
ϵ_s = deformation modulus of ground in shear;
ν = ratio of $\frac{y_t}{y_s}$;
λ = ratio of $\frac{y_r}{y_s}$;
ψ = ratio of $\frac{\phi_g}{\phi_R}$;
α^2 = dynamic shearing constant of beam $= \frac{Y_s\,w}{g\,G\,A}\left(\frac{\text{seconds}^2}{\text{length}^2}\right)$;
β^2 = dynamic flexural constant of beam $= \frac{w}{g\,E\,I_x}\left(\frac{\text{seconds}^2}{\text{length}^4}\right)$;
p = time-frequency $\left(\frac{\text{radians}}{\text{second}}\right)$;
q = trigonometric space-frequency $\left(\frac{\text{radians}}{\text{length}}\right)$;
r = hyperbolic space-frequency $\left(\frac{\text{radians}}{\text{length}}\right)$;
u = space-frequency for case of flexure only $= \sqrt{\beta\,p}\left(\frac{\text{radians}}{\text{length}}\right)$;
ρ = beam parameter $= \frac{\beta^2}{\alpha^4}$ (seconds^{-2});
$f(z)$ = transverse loading intensity a function of z;
V = shear in beam;
M = moment in beam;
Z = normal space-function;
$f(t)$ = trigonometric function of time;
$A\,B\,C\,D$ = temporary constants of integration;
T = natural period of vibration (seconds);

T_1 = fundamental natural period;
T_n = nth mode natural period;
T_s = isolated natural period due to shear distortions only;
T_f = isolated natural period due to flexural distortions only;
T_{sf} = natural period due to shear and flexure, rigid ground;
T_{sftr} = natural period due to shear, flexure, and elastically yielding ground;
T_R = natural torsional period of beam or building; rigid ground;
T_{Rg} = natural torsional period of beam or building; yielding ground;
$T_a\,T_b \cdots$ = isolated component periods; general case; and,
T_r = resultant period of several isolated component periods.

APPENDIX II

Natural Frequencies of a Cantilever Beam Subjected to Shear as Well as to Flexure and with Elastic Constraints at the Built-In End

It will be assumed that the principle of superposition of distortions is valid so that the simple theories of beam deflections may be expressed as follows:

Intensity of loading,

$$f(z) \qquad (29a)$$

Gradient of shear,

$$\frac{\partial V}{\partial z} = -f(z) \qquad (29b)$$

Variation of gradient of moment,

$$\frac{\partial^2 M}{\partial z^2} = -f(z) \qquad (29c)$$

Curvature of beam,[13]

$$\frac{\partial^2 y}{\partial z^2} = -\frac{M}{E\,I_x} - \frac{Y_s}{G\,A} f(z) \qquad (29d)$$

Variation of curvature of beam,

$$\frac{\partial^3 y}{\partial z^3} = -\frac{V}{E\,I_x} - \frac{Y_s}{G\,A}\frac{\partial f(z)}{\partial z} \qquad (29e)$$

Second variation of curvature,

$$\frac{\partial^4 y}{\partial z^4} = \frac{f(z)}{E\,I_x} - \frac{Y_s}{G\,A}\frac{\partial^2 f(z)}{\partial z^2} \qquad (29f)$$

The investigation will be limited to a consideration of the case in which the shearing rigidity, $\frac{G\,A}{Y_s}$, the flexural rigidity, $E\,I_x$, and the weight per unit length, w, are constants for the beam. If the beam is set into vibration, the loading intensity is dynamic, and may be expressed as follows:

---

[13] "Strength of Materials," by S. Timoshenko, Pt. I, p. 187.

$$f(z) = -\frac{w}{g}\frac{\partial^2 y}{\partial t^2} \qquad (30)$$

Substituting Equation (30) into Equation (29*f*), the general differential equation for the motion of the beam is obtained, as follows:

$$\frac{\partial^4 y}{\partial z^4} = -\frac{w}{g\,E\,I_x}\frac{\partial^2 y}{\partial t^2} + \frac{Y_s\,w}{g\,G\,A}\frac{\partial^4 y}{\partial z^2\,\partial t^2} = -\beta^2\frac{\partial^2 y}{\partial t^2} + \alpha^2\frac{\partial^4 y}{\partial z^2\,\partial t^2} \qquad (31)$$

Equation (31) takes into account the effect of shear as well as of bending moment on the elastic distortions, but it neglects the effect of rotatory inertia on the dynamic loading. The dimensions of β are seconds per unit length^2, whereas those of α are seconds per unit length.

If one assumes that the solution of Equation (31) is given by a normal function, Z, so that:

$$y = Z\,f(t) = Z\,(E\cos p\,t + F\sin p\,t) \qquad (32)$$

then Equation (32) may be substituted in Equation (31) with the result that the differential equation for Z becomes:

$$\frac{\partial^4 Z}{\partial z^4} + \alpha^2\,p^2\frac{\partial^2 Z}{\partial z^2} - \beta^2\,p^2\,Z = 0 \qquad (33)$$

Equation (33) is a linear differential equation, and yields the following solution:

$$y = (A\cos q\,z + B\sin q\,z + C\cosh r\,z + D\sinh r\,z)\,f(t) \qquad (34)$$

subjected to the restriction that q^2 and r^2 must satisfy the following quadratic equations,

$$q^4 - \alpha^2\,p^2\,q^2 - \beta^2\,p^2 = 0 \qquad (35a)$$

and,

$$r^4 + \alpha^2\,p^2\,r^2 - \beta^2\,p^2 = 0 \qquad (35b)$$

This means that:

$$q = \frac{\alpha\,p}{\sqrt{2}}\sqrt{\sqrt{1 + \frac{4\,\rho}{p^2}} + 1} \qquad (36a)$$

and,

$$r = \frac{\alpha\,p}{\sqrt{2}}\sqrt{\sqrt{1 + \frac{4\,\rho}{p^2}} - 1} \qquad (36b)$$

in which the units are radians per unit length. The parameter, ρ (in radians per second)^2 is defined as follows:

$$\rho = \frac{\beta^2}{\alpha^4} = \frac{g\,G^2\,A^2}{Y_s^{\,2}\,w\,E\,I_x} \qquad (37)$$

Thus, for the case in which the beam distortions are due to shear only, $\rho = 0$; $r = 0$; and $q = \alpha\,p$, in radians per unit length. If the distortions of the beam were due to flexure only, the value of ρ would approach infinity; and, $r = q = \sqrt[4]{\rho\,\alpha^4\,p^2} = \sqrt{\beta\,p} = u$.

If the origin of the co-ordinate axes is placed at the free end of the beam, (see Fig. 1) the following end conditions prevail: At the free end where $z = 0$, the moment must be zero, hence from Equations (29*d*) and (30):

$$\left(\frac{\partial^2 y}{\partial z^2}\right)_{z=0} = \alpha^2 \left(\frac{\partial^2 y}{\partial t^2}\right)_{z=0} \qquad \text{(38a)}$$

Moreover, at the free end the shear must be zero, hence from Equations (29*e*) and (30):

$$\left(\frac{\partial^3 y}{\partial z^3}\right)_{z=0} = \alpha^2 \left(\frac{\partial^3 y}{\partial t^2\,\partial z}\right)_{z=0} \qquad \text{(38b)}$$

At the built-in end where $z = L$ the shear, $V_{z=L}$, acting upon the ground of translatory rigidity, R_y, will produce a displacement,

$$(y)_{z=L} = \frac{V_{z=L}}{R_y} = -\frac{1}{R_y}\int_0^L f(z)\,dz = \frac{w}{g\,R_y}\int_0^L \frac{\partial^2 y}{\partial t^2}\,dz$$

$$= \tau \int_0^L \frac{\partial^2 y}{\partial t^2}\,dz \qquad \text{(39)}$$

Moreover, the slope of the beam at the built-in end is due to the shear in the beam itself as well as to the rotation of the ground. This rotation depends on the moment exerted by the beam upon the ground and on the rotatory rigidity, $R_{y\theta}$, of the ground itself. The shear contribution to the slope at $z = 0$ is:

$$\left(\frac{\partial y_s}{\partial z}\right)_{z=L} = \frac{Y_s\,V_{z=L}}{G\,A} = -\frac{Y_s}{G\,A}\int_0^L f(z)\,dz$$

$$= \frac{Y_s\,w}{g\,G\,A}\int_0^L \frac{\partial^2 y}{\partial t^2}\,dz = \alpha^2 \int_0^L \frac{\partial^2 y}{\partial t^2}\,dz \qquad \text{(40a)}$$

Whereas the contribution due to the rotation of the ground is:

$$\left(\frac{\partial y_r}{\partial z}\right)_{z=L} = \frac{M_{z=L}}{R_{y\theta}} = -\frac{1}{R_{y\theta}}\int_0^L \int f(z)\,dz\,dz$$

$$= +\frac{w}{g\,R_{y\theta}}\int_0^L \int \frac{\partial^2 y}{\partial t^2}\,dz\,dz = +\zeta \int_0^L \int \frac{\partial^2 y}{\partial t^2}\,dz\,dz \qquad \text{(40b)}$$

Consequently:

$$\left(\frac{\partial y}{\partial z}\right)_{z=L} = \left(\frac{\partial y_s}{\partial z}\right)_{z=L} + \left(\frac{\partial y_r}{\partial z}\right)_{z=L} = \alpha^2 \int_0^L \frac{\partial^2 y}{\partial t^2}\,dz$$

$$+ \zeta \int_0^L \int \frac{\partial^2 y}{\partial t^2}\,dz\,dz \qquad \text{(41)}$$

From the first two end conditions given by Equations (38),

$$C = \frac{r^2}{q^2} A \qquad \text{(42a)}$$

and,

$$D = \frac{r}{q} B \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (42b)$$

If Equations (42) are introduced into Equation (34), the following expression for y will be obtained:

$$y = \left[A \left(\cos q\, z + \frac{r^2}{q^2} \cosh r\, z \right) + B \left(\sin q\, z + \frac{r}{q} \sinh r\, z \right) \right] f\,(t) \ldots (43)$$

The constants, A and B, depending on end conditions, are complicated and will not be evaluated here, but the frequency equation, resulting from substituting Equation (43) into the expressions for the end conditions at the built-in end (that is, into Equations (39) and (41)), assumes the form:

$$\begin{aligned} &2\,\alpha^4\,\rho + 2\,\tau\,\zeta\,p^2 \\ &+ (2\,\alpha^4\rho - 2\,\tau\,\zeta\,p^2 + \alpha^4\,p^2) \cos q\,L \cosh r\,L \\ &+ \left(+ \frac{\zeta}{r} - \tau\,r \right) \alpha^2\,p^2 \sqrt{1 + \frac{4\,\rho}{p^2}} \cos q\,L \sinh r\,L \\ &+ \left(- \frac{\zeta}{q} - \tau\,q \right) \alpha^2\,p^2 \sqrt{1 + \frac{4\,\rho}{p^2}} \sin q\,L \cosh r\,L \\ &+ \left(- \frac{\tau\,\zeta}{\sqrt{\rho}} p^2 - \alpha^4 \sqrt{\rho} \right) p \sin q\,L \sinh r\,L = 0 \ldots\ldots\ldots (44) \end{aligned}$$

The frequency equation, of course, is rather involved, containing either explicitly or implicitly the four constants: α and β for the beam itself, and τ and ζ for the ground.

DISCUSSION OF FREQUENCY EQUATION

It will now be shown that a number of particular cases for some of which the frequency equations are well known, can be derived from the general frequency formula, Equation (44).

Case a.—If the ground is assumed to be rigid in translation as well as in rotation, τ and ζ are zero and the general equation reduces to:

$$\cos q\,L \cosh r\,L - \frac{p\,\sqrt{\rho}}{p^2 + 2\,\rho} \sin q\,L \sinh r\,L = - \frac{2\,\rho}{p^2 + 2\,\rho} \ldots\ldots (45)$$

Therefore, Equation (45) will give the frequencies for the transverse modes of vibration of a cantilever beam rigidly built-in when shear distortions as well as flexural distortions are present (see Table 3(a)).

Case a_1.—If the problem is simplified further and the shear deformations of the beam are assumed to be negligible in comparison with the flexural deformations, Equations (37) and (36) show that $\rho = \infty$, $q = r$, and $r = \sqrt{\beta\,p} = u$. Equation (45) then reduces to the well known frequency equation for a slender cantilever beam, namely:

$$\cos u\,L \cosh u\,L = - 1 \ldots\ldots\ldots\ldots\ldots\ldots (46a)$$

TABLE 3.—RATIOS OF TRUE PERIODS, T, TO PERIODS COMPUTED ON ASSUMPTIONS OF SHEAR ONLY (T_s) AND ON ASSUMPTIONS OF FLEXURE ONLY (T_f); CANTILEVER BEAM RIGIDLY BUILT-IN

EQUATIONS TO EXPRESS MODES OF VIBRATION:

(a) Fundamental Mode of Vibration,

$$T_1 = \left(\frac{T}{T_s}\right)_1 0.288\sqrt{y_s};\quad \text{or,}\quad T_1 = \left(\frac{T}{T_f}\right)_1 0.258\sqrt{y_f}$$

(b) Second Mode of Vibration,

$$T_2 = \left(\frac{T}{T_s}\right)_2 0.0960\sqrt{y_s};\quad \text{or,}\quad T_2 = \left(\frac{T}{T_f}\right)_2 0.0412\sqrt{y_f}$$

(c) Third Mode of Vibration,

$$T_3 = \left(\frac{T}{T_s}\right)_3 0.0576\sqrt{y_s};\quad \text{or,}\quad T_3 = \left(\frac{T}{T_f}\right)_3 0.0147\sqrt{y_f}$$

(d) Fourth Mode of Vibration,

$$T_4 = \left(\frac{T}{T_s}\right)_4 0.0411\sqrt{y_s};\quad \text{or,}\quad T_4 = \left(\frac{T}{T_f}\right)_4 0.0075\sqrt{y_f}$$

Case a_2.—If the problem had been simplified by assuming that flexural deformations of the beam were negligible in comparison with shear deformations, Equations (37) and (36) would have given $\rho = 0$, $r = 0$, and $q = \alpha\, p$, and the frequency Equation (45) would have reduced to:

$$\cos \alpha\, p\, L = 0 \quad \text{(46b)}$$

This is the frequency equation for a stubby beam when shear alone is of importance. If the constant, α, had been made to refer to torsional vibrations instead of to translational shear vibrations, the same frequency equation would hold.

Case b.—Going to the other extreme in regard to the character of the end fastening and assuming that the cantilever beam becomes a free beam, the ground constants, τ and ζ, must approach infinity, and the general frequency equation reduces to:

$$\cos q\, L \cosh r\, L + \frac{p}{2\sqrt{\rho}} \sin q\, L \sinh r\, L = 1 \quad \text{(46c)}$$

This equation applies to the frequencies of free beams as, for instance, the bars used in xylophones. Flexure as well as shear is considered.

Case b_1.—Simplifying Equation (46*c*) further by assuming that flexure alone is of consequence:

$$\cos u\, L \cosh u\, L = 1 \quad \text{(46d)}$$

another well-known result.

Case b_2.—If the free beam is very stubby, shear alone governs the frequencies and Equation (46*c*) reduces to:

$$\cos \alpha\, p\, L = 1 \quad \text{(46e)}$$

This type of frequency equation also applies to the torsional or to the longitudinal vibrations of a free bar.

Case c_1.—If the hypothetical situation of a ground, yielding elastically in translation but infinitely rigid in rotation is to be considered, $\zeta = 0$, and $\tau \neq 0$. Then for the case in which shear alone is of importance the general frequency equation (44) would reduce to:

$$\tan \alpha\, p\, L = \frac{\alpha}{p\, \tau} \quad \text{(47a)}$$

This type of equation also applies to the torsional vibrations of cantilever beams with elastic torsional end constraint (see Fig. 5).

Case c_2.—If the translatory rigidity vanishes, τ approaches infinity while the rotatory ground rigidity remains infinite (that is, $\zeta = 0$); the result for flexure alone then becomes:

$$\tan u\, L = -\tanh u\, L \quad \text{(47b)}$$

Case c_3.—The result for shear alone assumes the form:

$$\tan \alpha\, p\, L = 0 = \sin \alpha\, p\, L \quad \text{(47c)}$$

Case d_1.—An equally hypothetical case of a ground yielding elastically in rotation, but being infinitely rigid in translation would give for shear alone,

$$\tan \alpha\, p\, L = \frac{\alpha^3\, p}{\zeta} \qquad (47d)$$

Case d_2.—Again, if the rotatory rigidity were to vanish completely, ζ must approach infinity and the result is a beam with a hinge at one end. Under these circumstances flexural considerations alone would give:

$$\tan u\, L = \tanh u\, L \qquad (47e)$$

Case d_3.—Shear alone gives:

$$\tan \alpha\, p\, L = 0 \qquad (47f)$$

APPENDIX III

A CRUDE, RATIONAL ANALYSIS OF THE ELASTIC CONSTRAINING ACTION OF THE GROUND OF A CANTILEVER BEAM OR IDEALIZED BUILDING

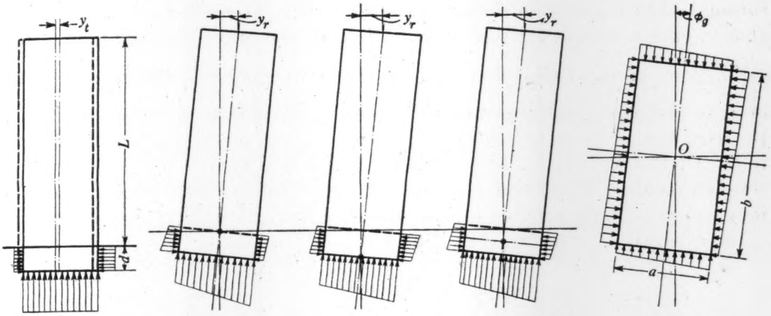
In regard to the "fixed"-end conditions of the cantilever beam, it was assumed that the medium in which it is "planted" is a semi-infinite elastic continuum; further assumptions can now be made, namely, that the inertia properties of the continuum may be neglected, and that the interaction pressures between the medium and the cantilever beam are linearly distributed over the contact surfaces involving ignorable discontinuities at edges and at corners. It is true that these assumptions are very crude, and that some doubt exists in regard to their validity even as first approximations to reality.

For purposes of analysis one may recognize three ground deformation moduli, a vertical ϵ_v, a horizontal ϵ_h, and over the base of the cantilever a shear modulus ϵ_s. These moduli differ from moduli of elasticity in being expressed in stress per total deformation; that is, in pounds per cubic inch instead of in pounds per square inch. The translatory rigidity of the ground in the Y-direction (in pounds per inch) is then given by:

$$R_y = 2\, \epsilon_h\, b\, d + \epsilon_s\, a\, b \qquad (48)$$

The corresponding horizontal translation, y_t, due to a hypothetical horizontal loading of the cantilever will be constant for the entire height of the beam (see Fig. 9(*a*)) and will be as expressed by Equation (18).

Directing attention to the rotation of the center line of the cantilever resulting from the same hypothetical loading as before, the investigator is confronted with some uncertainty in regard to the location of the center of rotation. Figs. 9(*b*), 9(*c*), and 9(*d*) indicate three possible locations of this center with the resulting pressure distributions over the contact surfaces. If the elastic restoring moment of the ground per unit angular rotation is evaluated for the three positions of the center of rotation, they will be found to increase as the center moves downward, but the resulting linear translations of the top of the cantilever, corresponding to the ground influence on a fundamental mode, will not differ as much as the angles. For this reason the question of the exact location of the rotation center may be dismissed, assuming that it lies in the plane of the ground surface as shown in Fig. 9(*b*). The rotatory rigidity of the ground for this location is given, in pound-inches per radian, by:



(*a*) ELASTIC TRANSLATION, y_t

(*b*) ELASTIC TILTING, y_r
Rotation Center at Ground Surface

(*c*) ELASTIC TILTING, y_r
Rotation Center at at End of Beam

(*d*) ELASTIC TILTING, y_r
Rotation Center Between (*b*) and (*c*)

(*e*) ELASTIC TORSION, ϕ_g

FIG. 9.—SIMPLIFIED DIAGRAMS OF GROUND PRESSURE DISTRIBUTIONS AT END OF CANTILEVER BEAM SUBJECTED TO ELASTIC DEFORMATION OF GROUND

$$R_{y\theta} = \epsilon_v \frac{a^3\, b}{12} + \epsilon_h \frac{2\, b\, d^3}{3} \qquad \text{(49}a\text{)}$$

and,

$$R_{x\theta} = \epsilon_v \frac{a\, b^3}{12} + \epsilon_h \frac{2\, a\, d^3}{3} \qquad \text{(49}b\text{)}$$

to which the corresponding horizontal translations of the top of the beam (y_r and x_r, in inches), are expressed by Equation (19).

Finally, the torsional rigidity of the ground is considered for a hypothetical twisting moment of $w\, k$ lb-in. per unit height of the beam. Fig. 9(*e*) shows the resulting pressure distributions on the vertical surfaces or basement walls of the beam, and the torsional rigidity coefficient of the ground (in pound-inches per radian) is easily shown to be:

$$R_\phi = \epsilon_h \frac{1}{6} (a^3 + b^3)\, d + \epsilon_s \frac{1}{12} (a\, b^3 + a^3\, b) \qquad (50)$$

which corresponds to an angle of twist of the beam (ϕ_g), in the ground itself which is expressed by Equation (20).

A few words in regard to the relative values of the deformation moduli are appropriate if the theory must be simplified.

If the ground medium is homogeneous and isotropic, the values of ϵ_h, ϵ_v, and ϵ_s are related to: (1) The two elastic constants, E and $\frac{1}{m}$; (2) the dimensions of the cross-section; and (3) the depth of "planting." On the other hand, if the ground medium is ordinary soil it becomes very difficult to make any theoretical predictions of the values of the ground deformation moduli.

Since the medium, or soil under the beam or building, is usually highly consolidated compared to the soil adjacent to the basement walls, it is reasonable to expect that ϵ_v is much greater than ϵ_h; the order of magnitude of the ratio, $\gamma = \frac{\epsilon_v}{\epsilon_h}$, may well lie between the values 10 and 100. The relative value of ϵ_s is perhaps equally problematic since it depends to a certain extent on the frictional adhesion of the soil to the base. However, it would be reasonable to expect that ϵ_s is of the same order of magnitude as ϵ_h. With the object of simplification in mind, and for want of better information, the investigator may choose to make ϵ_s equal to ϵ_h. The simplified expressions for the rigidities (compared with Equations (48), (49), and (50)) are then:

$$R_y = \epsilon_h \,(2\,b\,d + a\,b) \qquad \text{(51}a\text{)}$$

$$R_x = \epsilon_h \,(2\,a\,d + a\,b) \qquad \text{(51}b\text{)}$$

$$R_{y\theta} = \epsilon_h \frac{1}{12}\, b\,(\gamma\, a^3 + 8\,d^3) \qquad \text{(51}c\text{)}$$

$$R_{x\theta} = \epsilon_h \frac{1}{12}\, a\,(\gamma\, b^3 + 8\,d^3) \qquad \text{(51}d\text{)}$$

$$R_\phi = \epsilon_h \frac{1}{6}\left[(a^3 + b^3)\,d + \frac{1}{2}\,(a\,b^3 + a^3\,b)\right] \qquad \text{(51}e\text{)}$$

The chief value of this analysis is to recognize that since there are five rigidities R_x, R_y, $R_{x\theta}$, $R_{y\theta}$, and R_ϕ expressed by the ground deformation constant, ϵ_h, and the ratio, γ, plus the dimensions of the basement, a, b, and d, the following relations are determined for the rigidities:

$$R_y = \frac{b\,(24\,d + 12\,a)}{2\,(a^3 + b^3)\,d + (a\,b^3 + a^3\,b)}\, R_\phi \qquad \text{(52}a\text{)}$$

$$R_x = \frac{a\,(24\,d + 12\,b)}{2\,(a^3 + b^3)\,d + (a\,b^3 + a^3\,b)}\, R_\phi \qquad \text{(52}b\text{)}$$

$$R_y = \frac{b\,(2\,d + a)}{a\,(2\,d + b)}\, R_x \qquad \text{(52}c\text{)}$$

$$R_{y\theta} = \frac{\gamma\, a^3 + 8\,d^3}{24\,d + 12\,a}\, R_y \qquad \text{(52}d\text{)}$$

$$R_{x\theta} = \frac{\gamma\, b^3 + 8\,d^3}{24\,d + 12\,b}\, R_x \qquad \text{(52}e\text{)}$$

$$R_{y\phi} = \frac{b\,(\gamma\, a^3 + 8\,d^3)}{a\,(\gamma\, b^3 + 8\,d^3)}\, R_{x\phi} \qquad \text{(52}f\text{)}$$

The hypothetical static displacements are then related as follows:

$$y_r = \frac{(12\,d + 6\,a)\,L^2}{\gamma\,a^3 + 8\,d^3}\,y_t \qquad (53a)$$

$$x_r = \frac{(12\,d + 6\,b)\,L^2}{\gamma\,b^3 + 8\,d^3}\,x_t \qquad (53b)$$

$$\phi_g = \frac{12\,R\,(2\,b\,d + a\,b)}{2\,(a^3 + b^3)\,d + (a\,b^3 + a^3\,b)}\,y_t \qquad (53c)$$

and,

$$\phi_a = \frac{12\,R\,(2\,a\,d + a\,b)}{2\,(a^3 + b^3)\,d + (a\,b^3 + a^3\,b)}\,x_t \qquad (53d)$$

If two independent rigidities can be found from a study of observed periods, the remaining three follow. It must be remembered, however, that only in rare instances are the two ground deformation constants, ϵ_h and γ, sufficient for expressing the conditions of the soil around a building, because not only geological features, but also man-made constructions, as exemplified by the proximity of other buildings, will generally call for different values of ϵ_h on the different basement walls; in addition to this complication, ϵ_v may vary over the foundation, especially if a spread footing foundation is adopted.

Influence of the Ground on the Torsional Periods

It was mentioned previously that flexure does not complicate the problem of determining the periods of torsion. In regard to the effect of the ground on these periods a similar simplification exists since the vertical deformation constant, ϵ_v, and, consequently, the ground rotation, do not enter into the problem. Equations (1*b*), (4*b*), and (21) enable one to define the ratio of the torsional yielding of the ground to that of the beam as follows:

$$\psi = \frac{\phi_g}{\phi_R} = \frac{12\,b\,(2\,d + a)}{2\,(a^3 + b^3)\,d + (a\,b^3 + a^3\,b)}\,\frac{Y_s\,R_t}{A}\,\frac{y_t}{y_s} \qquad (54)$$

DISCUSSION

K. BERT HIRASHIMA,[14] ESQ. (by letter).—This interesting paper by Professor Jacobsen should prove an important addition to the literature of the subject treated. Especially valuable are the tables and graphs illustrating the theory.

The normal modes of transverse vibrations of a rigidly built-in cantilever, resulting from a consideration of shear only and flexure only, are well known. Taking the frequency equation for each of these two elementary cases, the vibrations that occur in the Y-direction are given by Equations (7) and (10). It will seem that Equation (7) (shear only considered) is comparatively simple and easy to solve. The solution of Equation (10) (flexure only) is more complicated; but it can be solved by a method of successive approximations.[15]

However, as shown in the paper, neither of these comparatively simple equations gives the correct result for the general case in which neither shear nor flexure is negligible. Thanks to Table 3, however, the periods of the various modes for this general case can readily be obtained by simple multiplication from the solution of either equation. Equation (7) will probably be preferable for reasons of simplicity.

The author's analysis of the effect on the vibration periods of the elastic yielding of the ground is highly interesting; but the solution of the frequency equation for this case is very involved. However, Table 2 and the graphs in Figs. 6, 7, and 8, give a clear indication of what can be expected when the ground yields elastically. The ground deformation moduli, ϵ_v, ϵ_h, and ϵ_s, of course, can be determined by experimental methods. The ground rigidities, R_x, R_y, $R_{x\theta}$, $R_{y\theta}$, and R_ϕ, can then be determined in the manner described in the paper. Finally, with numerical values of the ground constants thus determined the frequency equation can be solved for the values of the various periods. The disadvantage of the foregoing procedure is that it is long and tedious with the likelihood that errors will be introduced.

In practical engineering work, as differentiated from theoretical investigations, what is most desired is not 100% theoretical accuracy, but an accuracy sufficient for the nature and needs of the problem. With this standard limitation in mind it seems that a table similar to Table 3 could be constructed giving conversion factors for various types of soils and foundations. The period of the various modes for a cantilever "planted" in sandy soil, for example, can then be determined by simple multiplication from the solution of either Equation (7) or Equation (10); or, by reference to Tables 2 and 3 and Figs. 6, 7, and 8, the engineer could derive his own factors for converting the periods as obtained from a solution of Equation (7) or Equation (10) into the estimated true periods for the case of an elastically yielding ground. Such procedure requires sound judgment on the part of the engineer. The errors incident thereto are probably not more serious than the uncertainties inherent in the nature of the problem. On important work, investigation along the lines indicated in the paper is justified.

[15] "Applied Elasticity," by J. Prescott, p. 206.

It may be remarked that the various frequency equations, involving as they do either trigonometric or hyperbolic functions, have an infinite number of roots. When a rod (or, in the present case, a cantilever) is set in motion by being bent to one side and then released, it is not likely to begin vibrating in any one of the normal modes, unless the curve into which the cantilever is first bent was the same curve as the cantilever assumes in one of the extreme positions of that particular normal mode. However, it is known that the subsequent motion is composed of a number of superposed normal modes of which the lower modes are the more important.

The further discussion of the superposition of normal modes and the development in terms of Fourier's series is beyond the scope of the paper. The interested reader is referred to the various special treatises such as Byerly's "Fourier's Series and Spherical Harmonies"; Lord Rayleigh's "Theory of Sound"; Prescott's "Applied Elasticity"; and Love's "Mathematical Theory of Elasticity."

MERIT P. WHITE,[16] JUN. AM. SOC. C. E. (by letter).—Since this paper is intended primarily for the designer of earthquake-resistant buildings, a question arises as to the errors involved in treating an ordinary building, even one of constant cross-section, as a uniform cantilever beam with definite shear and bending flexibility. On the other hand, even a very simple building is a tremendously complicated elastic-dynamic system. The interaction of frame, walls, and partitions, the variations in stiffness of these elements due to doors and windows, the concentrations of mass at the floor levels—these and similar factors make impossible any mathematically exact analysis. Obviously, in order to secure any information at all on the dynamical characteristics of a building many simplifying assumptions are necessary.

In his "Synopsis" the author states that close agreement with actuality is not to be expected if the theory is applied to buildings. The writer agrees with this statement to the following extent: Certainly, any one possessing only a complete set of plans for a given building, including data on the deformation characteristics of the site, and with no empirical information obtained by observations on similar buildings on similar sites, would be fortunate indeed to be able to predict within 20% the fundamental period of the building in question. On the other hand, possession of the empirical information just mentioned would permit a much closer prediction of the building period. Furthermore, there are certain other, very important quantities, such as the shapes of the several modes of vibration, the relation between the fundamental period and the periods of higher modes, and the change in building period due to foundation yielding, all of which, the writer believes, can be determined with considerable accuracy from the theory presented by Professor Jacobsen.

Although it is quite true that an ordinary building is so complicated that any attempt to make a mathematically exact analysis in an endeavor to test the validity of the author's simplifying assumptions would be an endless task, nevertheless it may be possible to check these assumptions by making others, quite different, and performing the calculation which they make possible.

---

[16] Research Asst., California Inst. of Technology, Pasadena, Calif.

The author simplified his problem by replacing discontinuous distributions of weight and stiffness by continuous functions. Actually, these characteristics were considered constant. Another possible simplification would be the following: Consider all weights to be concentrated at the floors, and replace the stiffness of frame, walls, and partitions by fixed-ended columns. It must not be thought that the fixed-ended columns in the proposed model are identical with the columns of the real building. Actually, they are much stiffer because the greatest part of the lateral stiffness of an ordinary building is due to its walls and partitions. This can be shown by comparing measured building periods with those computed, neglecting the stiffening of the walls. These hypothetical columns are purely schematic and are intended to duplicate the stiffness, and not the structure, of a building.

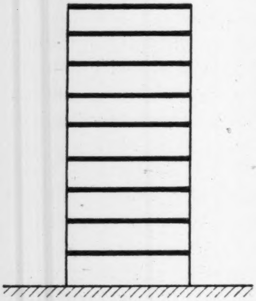

FIG. 10

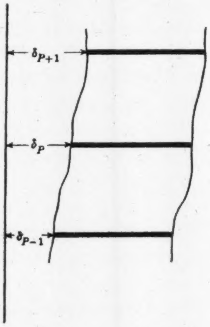

FIG. 11

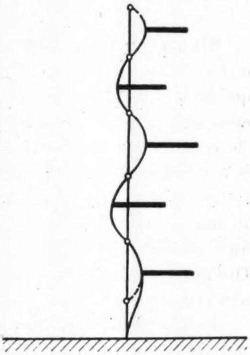

FIG. 12

Although this idealized building is no more real than that of the author, nevertheless, a comparison of the results of both assumptions will give an idea of their reliability, particularly since an actual building is somewhat intermediate in nature.

To simplify matters as much as possible, it will be assumed that: (1) Bending of the building as a whole (extension and compression of the hypothetical columns) is negligible; (2) foundation yielding is also negligible; (3) the weights of all floors are equal; and (4) all stories are equally stiff. Although these limitations detract much from the reality of the model, if the agreement in this very particular case is satisfactory, it may safely be assumed that the author's assumptions are generally permissible.

The following problem is to be solved: To find expressions for the frequencies of the several modes of vibration of the structure shown in Fig. 10, consisting of a given number (N) of floors, each of Mass m, supported by columns giving a stiffness, K, to each story (K is the force, in pounds, which will produce unit relative deflection between two adjacent floors). Since N quantities (the deflections of the several masses, for example) are necessary to describe the configuration of the system completely at any instant, the system is said to have N degrees of freedom. Thus, there will be N different modes and frequencies of vibration which can be calculated by solving a system of N simultaneous linear equations.

Except for the boundary condition at the roof, this problem is identical with that of finding the modes and frequencies of vibration of a series of identical, equally spaced beads on a stretched string, first solved by Lagrange.[17] In fact the solutions to the present problem are identical with half the solutions of Lagrange, those possessing an even number of nodes or an odd number of half waves. This follows from the fact that the boundary condition at the top of a vibrating building—namely, that at this point the shear is zero—is satisfied at the center of a vibrating string of beads provided this point is not a node. The computation is quite simple.

Assume that the system shown in Fig. 10 is vibrating in any one of its normal modes (fundamental, second harmonic, etc.). In such a vibration each point moves with simple harmonic motion, of frequency, f_n, this being the natural frequency of the mode in question (the nth mode). Furthermore, in any normal vibration all points move in phase; that is, they pass through their extreme positions simultaneously. If δ_p is the amplitude of motion of the pth mass, then its displacement at any instant is,

$$\Delta = \delta_p \sin (\lambda_n t - \xi_n) \quad \text{.....................} (55)$$

in which ξ_n is the phase angle for the nth mode of vibration and is the same for all points of the structure; and, λ_n is equal to $2 \pi f_n$. By differentiating the expression for displacement, it can be shown that the acceleration of the pth mass is: $- \lambda_n^2 \delta_p \sin (\lambda_n t - \xi_n)$. This acceleration is always equal to λ_n^2 times the displacement and is in the opposite direction.

The present problem is to determine f_n—in other words, to calculate the frequency of the nth mode of vibration. Fig. 11 shows the masses at the points, $p - 1$, p, and $p + 1$, in their extreme positions. Consider the equilibrium of the pth mass on which the following forces act: (1) A D'Alembert force equal to mass times acceleration; (2) a force due to bending of the columns above; and (3) the same due to the columns below.

For the pth mass,

$$m \lambda_n^2 \delta_p + K (\delta_{p+1} - 2 \delta_p + \delta_{p-1}) = 0 \quad \text{...........} (56a)$$

For the mass at the top (the Nth),

$$m \lambda_n^2 \delta_N + K (- \delta_N + \delta_{N-1}) = 0 \quad \text{..............} (56b)$$

and, for the lowest mass (the first),

$$m \lambda_n^2 \delta_1 + K (\delta_2 - 2 \delta_1) = 0 \quad \text{................} (56c)$$

---

[17] "Mechanique Analytique," by Joseph L. Lagrange, Tome I, p. 390.

Making $2 - \frac{m}{K}\lambda_n^2 = C$, the complete set of N-equations can be written:

$$\left.\begin{array}{l} C\,\delta_1 - \delta_2 = 0 \\ -\delta_1 + C\,\delta_2 - \delta_3 = 0 \\ -\delta_2 + C\,\delta_3 - \delta_4 = 0 \\ \cdots\cdots\cdots\cdots\cdots \\ -\delta_{N-2} + C\,\delta_{N-1} - \delta_N = 0 \\ -\delta_{N-1} + (C-1)\,\delta_N = 0 \end{array}\right\}\ldots(57)$$

The homogeneity of Equations (57) arises from the fact that all terms contain δ. Thus, the shape, but not the absolute dimensions, of the mode of vibration can be found. One of the δ-ratios will remain arbitrary. The remaining δ-ratios and C are the N unknowns to be determined.

Several methods exist for finding the natural frequencies of the given system from Equations (57). The usual procedure in such a case is based on the fact that the determinant of the coefficients of the unknown amplitudes must be zero in order that the δ-amplitudes may be different from zero. Since the coefficients of the δ-ratios involve only C and unity, it is clear that a single algebraic equation (identical with the determinant of the coefficients) can be obtained. This will be an Nth degree equation in C, the N roots (or solutions) of which will correspond to the N frequencies of the system. By making certain trigonometric substitutions, expressions for the frequencies in the general case (that is, in terms of N) can be found.

A somewhat simpler method, described by Professor A. G. Webster,[18] is the following: The quantity, $C\left(= 2 - \frac{m}{K}\lambda_n^2\right)$, is always less than $+\,2$. This is obvious since m, K and λ_n^2 are all positive. The least value of C occurs with maximum $\lambda_n\ (= \lambda_N)$. This corresponds to a mode (deflection curve) in which alternate masses are deflected in opposite directions as shown in Fig. 12. The frequency in this case is slightly less than it would be if all columns were pinned at their centers (including a half-column added at the top) as indicated in Fig. 12. Due to the pins, which allow rotation but not displacement of the center point of each column, certain constraints would be imposed on the system, thus raising its frequency. In the case of the pinned columns it is seen that the system is equivalent to N one-degree-of-freedom systems, each of frequency, $\lambda' = 2\sqrt{\frac{K}{m}}$. Since $\lambda_N < \lambda'$, it follows that $-\,2 < C < +\,2$.

On examining Equations (57) it is seen that each equation except the last resembles the trigonometric equation relating the sines of three consecutive multiples of an angle, θ:

$$-\sin(r-1)\,\theta + 2\cos\theta\sin r\,\theta - \sin(r+1)\,\theta = 0\ldots\ldots(58)$$

Resemblance becomes identity if: $\delta_r = A\sin r\,\theta$; and $C = 2\cos\theta$. This is permissible since $-\,2 < C < +\,2$. All equations except the Nth are satisfied by any value of θ. To satisfy the Nth equation, however, it is clear that only certain values of θ are possible. Rewriting the last of Equations (57):

---

[18] "Dynamics," by A. G. Webster, Second Edition, p. 167.

$$A\,[-\sin(N-1)\,\theta + 2\cos\theta\sin N\,\theta - \sin N\,\theta] = 0 \ldots\ldots (59)$$

since $-\sin(N-1)\,\theta + 2\cos\theta\sin N\,\theta - \sin(N+1)\,\theta = 0$,

$$\sin N\,\theta - \sin(N+1)\,\theta = 0 \ldots\ldots\ldots\ldots\ldots\ldots (60)$$

is the equation that determines possible values of θ. Therefore, $(2\,N+1)\,\theta = \pi, 3\,\pi, 5\,\pi \cdots (2\,n-1)\,\pi \cdots (2\,N-1)\,\pi$; and,

$$\theta = \frac{2\,n-1}{2\,N+1} \times \pi; \qquad n = 1, 2, 3 \cdots N \ldots\ldots\ldots\ldots (61)$$

Since $C = 2 - \frac{m}{K}\lambda_n^2 = 2\cos\theta = 2\cos\frac{2\,n-1}{2\,N+1}\,\pi$,

$$\lambda_n^2\,\frac{m}{K} = 2\left(1 - \cos\left(\frac{2\,n-1}{2\,N+1}\right)\frac{\pi}{2}\right) = 4\sin^2\left(\frac{2\,n-1}{2\,N+1}\right)\frac{\pi}{2} \ldots (62a)$$

and,

$$\lambda_n = 2\sqrt{\frac{K}{m}}\sin\left(\frac{2\,n-1}{2\,N+1}\right)\frac{\pi}{2}\,(n = 1, 2, 3, \cdots N) \ldots\ldots (62b)$$

For a system of N-masses there will be N-frequencies and modes of vibration, the former obtained by making $n = 1, 2, 3, \cdots N$, in Equation (62*b*).

If $\frac{n}{N}$ is small, Equation (62*b*) becomes approximately:

$$\lambda_n = \sqrt{\frac{K}{m}}\,\frac{2\,n-1}{2\,N}\,\pi\,(n = 1, 2 \cdots \ll N) \ldots\ldots\ldots\ldots (63)$$

TABLE 4.—VALUES OF $\frac{T}{\sqrt{y_s}}$ FOR DIFFERENT VALUES OF N (NUMBER OF STORIES) AND n (ORDER OF HARMONIC)

Values of of n	VALUES OF N						
	1	2	3	5	10	20	∞
1	0.320	0.299	0.294	0.290	0.289	0.288	0.288
2	....	0.115	0.105	0.100	0.097	0.096	0.096
3	....	....	0.073	0.063	0.059	0.058	0.058
4	....	....	....	0.049	0.043	0.042	0.041
5	....	....	....	0.043	0.035	0.033	0.032

Equation (63) may be compared with the author's Equations (8). In the present case:

$$y_s = \frac{m\,g}{K}\,(1 + 2 + 3 + \cdots N) = \frac{m\,g}{2\,K}\,(N^2 + N) \ldots\ldots\ldots (64)$$

in which y_s, as defined by the author, is the static deflection, in inches, due to a horizontal acceleration equal to g. If $N \ll N^2$ this gives, when substituted in Equation (63):

$$T_n = \frac{0.288}{2\,n - 1} \sqrt{y_s} \qquad (65)$$

which is equivalent to Equation (8). In terms of y_s, Equation (62*b*) becomes,

$$\lambda_n = \frac{2.772}{\sqrt{y_s}} \sqrt{N^2 + N} \sin\left(\frac{2\,n - 1}{2\,N + 1}\right)\frac{\pi}{2} \qquad (66)$$

and,

$$\frac{T_n}{\sqrt{y_s}} = \frac{0.226}{\sqrt{N^2 + N} \sin \frac{2n - 1}{2\,N + 1} \frac{\pi}{2}} \qquad (67)$$

Table 4 gives, for comparison, values of $\frac{T}{\sqrt{y_s}}$ for various values of n (order of harmonic) and N (number of floors in the structure). The last column ($N = \infty$) is from Equation (65) and corresponds to the values obtained by the author. It appears that even for structures of one or two stories the agreement is fairly close, while the lower frequencies in structures of several stories agree almost exactly with those given by the author's equations.

LYDIK S. JACOBSEN,[19] ESQ. (by letter).—As Mr. Hirashima states, tables with corrections for periods of buildings due to various types of foundations might be computed so as to make the designer's job of predetermining natural periods easier. However, for most of the practical designs, engineering judgment, fortified by qualitative knowledge of the relative importance of the different factors entering into the problem, will lead to results that are sufficiently accurate for design purposes. It must not be forgotten that the practical question relates to stresses in the building, and that it is only indirectly that natural periods of a structure merit study. Since the ground periods likely to be present in an earthquake are not definitely known, it is not necessary to predetermine the natural periods of the structure very accurately. The study presented in this paper attempts only to give quantitative backing for a sound evaluation of general tendencies; extensions from the specific examples given in the paper should rely chiefly on engineering judgment.

Mr. White's discussion of the paper introduces the question of the magnitude of error arising from considering continuous, rather than discontinuous, mass and rigidity distributions. He shows that for a highly simplified case satisfactory agreement is obtained if the structure consists of two or more stories. It should be pointed out, however, that the method used by Mr. White is definitely limited to a consideration of shear distortions and ground translations.

In the writer's opinion the effect of flexure of the building as a whole, as well as the effect due to ground tilting, may be estimated for most practical cases if one makes use of existing experimental data and is guided by a rational theory. In this case shear alone, or shear with estimated ground translation, becomes the only calculation that can reasonably be demanded by practice.

---

[19] Prof. of Mech. and Civ. Eng., Stanford Univ., Stanford University, Calif.

For this purpose a schedule form of calculation involving successive approximations, and first given by H. Holzer, enables the designer to calculate the natural periods of non-uniform buildings with considerable accuracy and ease. As an example of Holzer's method a torsional vibration problem has been solved by Professor Timoshenko.[20] The writer has used a slight modification of this method for dealing with non-uniform buildings, and it can be said that the amount of work is very small, even for a building of many stories, when it is compared to the customary static calculations for the idealized framework of a building.

CAUSES OF FAILURE IN HANDLING TRAFFIC

BY LEWIS W. MCINTYRE,[1] M. AM. SOC. C. E.

SYNOPSIS

The Bureau of Traffic Planning of the City of Pittsburgh, Pa., has conducted observations on down-town intersections to determine the space between moving automobiles, and also the time taken by automobiles to clear the intersection. Interference was at a minimum during these observations. The theoretical maximum traffic flow of a single lane of traffic was computed from these data. It is the purpose of this paper to show how various factors reduce the theoretical maximum traffic flow to the much lower values that occur in actual practice, in the usual congested district, and as far as possible to evaluate, quantitatively, the effect of each factor.

DEFINITIONS

The following definitions, essentially as proposed in 1934 by a Committee of the Institute of Traffic Engineers,[2] have been adopted for use in this paper:

(1) Traffic consists of pedestrians, mounted or herded animals, vehicles, street cars, and other conveyances together with their load, either singly or as a whole, while using any "way" for the purpose of transportation or travel.

(2) Traffic flow is the number of elemental components of traffic that pass a given point in a specified direction during a specified period of time (usually 1 hr). The traffic flow in an individual lane of traffic is determined by the effective headway and the speed.

(3) Traffic volume is the total number of elemental components of traffic that pass through a given intersection or way in any specified period of time (usually 8 hr, or more).

(4) Traffic capacity is the total number of elemental components of traffic that can pass through a given intersection or way in any specified period of time (usually 1 hr). The traffic capacity of any street depends upon the number of lanes of moving traffic on that street and the traffic flow in each individual lane.

(5) Traffic delay is the time spent while the elemental components of traffic that are being studied cannot move because of interference.

(6) Traffic speed is the rate of movement with which specified elemental components of traffic move over a specified course or section of way during any specified period.

(7) Over-all speed is the total distance traversed, divided by the total time required (usually expressed in miles per hour and includes all delays).

---

[1] Traffic consultant, Pittsburgh, Pa.

[2] Rept. of Committee on Terminology and Nomenclature, Inst. of Traffic Engrs., T. M. Matson, *Chairman*. Not published.

(8) Weaving is the movement of vehicular traffic in such manner that the elemental components cross each other's paths at low angles of approach or in nearly the same direction of movement.

(9) A point of conflict is the point or limited area where elemental component parts of traffic intersect; the apex of the angle of approach.

(10) A lane of traffic movement is a series of elemental components of traffic moving, or standing ready to move, so as to use a lane of roadway effectively.

(11) A critical lane is a line of traffic which, for inherent reasons, requires more time to pass a given point than other parallel lanes.

(12) The lane width of a roadway is the measure of the number of possible free moving lanes of traffic which the roadway can pass in both directions: (*a*) A lane is a width of roadway sufficient to accommodate the free movement of an average vehicle, customarily considered to be 10 ft.

(13) Headway is the time space between the front ends of vehicles or street cars when moving past a specified point in a given direction and lane.

(14) Minimum headway is the time space (see Definition (13)) obtained when the elemental components of traffic are moving as closely together as practicable.

(15) Effective headway is the time space (see Definition (13)) obtained for elemental components of traffic moving under minimum headway in one or more lanes.

(16) A way, as applied to traffic, is that upon which traffic passes. The term, "way," shall be considered generic to all places along which traffic may move. It includes highway, parkway, limited way, freeway, road, path, route, street, avenue, boulevard, lane, alley, arcade, drive, etc.

(17) A major street is a way that carries traffic between sections of an urban district. The major streets of a city are the main traveled ways. They may form important connecting links in the traffic facilities of the State. (A major street is sometimes referred to as an arterial street.)

(18) A minor street is a way that connects individual property with a major street or other minor streets.

(19) An alley is a narrow inner street, either without sidewalks, or with very narrow ones, or a street on which the rears of buildings adjoin. It serves as a connection with other minor streets.

(20) A radial street is a major street that runs from the central business district to the outlying districts of a city. A radial street signifies a way that carries traffic from surrounding territory to a main focal point. The term is also applied to rural highways.

(21) A distribution street is a major street that collects and passes traffic from the other major streets and from which traffic distributes itself to advantageous points of entry into a district.

(22) A by-pass street is a major street that carries traffic around congested districts (sometimes referred to as a belt line or loop).

(23) A cross-town street is a major "way" that carries traffic so as to intersect radial streets at approximately right angles. (A cross-town street is also referred to as circumferential street.)

(24) A roadway is that part of a way particularly devoted to vehicular traffic; ordinarily, it lies between the regularly established curb lines.

(25) The pavement is that part of a roadway having a constructed surface for the facilitation of vehicular traffic.

(26) An intersection is the area of a junction included within lines joining the meeting points of property lines (together with any sections of property lines necessary to enclose the area) at the junction of two or more ways at the same elevation.

(27) A congested district is any area in which most of the streets or ways carry such a volume of traffic during a considerable part of the day as materially to reduce the headway and cause traffic delay (usually a business district).

TABLE 1.—SPACE BETWEEN MOVING AUTOMOBILES AT INTERSECTIONS

No. of intersections	No. of observations	Average space, in feet	Remarks
3	574	17.82	Free movement
1	139	17.42	Following street car
1	71	12.8	Especially dense traffic

The spacing between vehicles (Table 1) was obtained by marking, on the street pavement, various distances from the property line. An observer recorded the distance of the rear end of each vehicle from the property line at the instant when the front end of a following vehicle passed this line. Under ordinary circumstances of fairly congested traffic, the average spacing between vehicles was 17.82 ft. When these vehicles followed street cars the space was 17.42 ft. In a number of cases where traffic was especially dense and was moving under obvious pressure, the spacing was as low as 12.8 ft. The data in Table 2 indicate that the first car of a group moved across the 36-ft roadway and one 12-ft sidewalk at an average speed of 10.8 or 10.9 miles per hr, depending on whether the vehicle was a passenger car or a truck. The data also indicate that following cars, because of their greater opportunity to get started, actually proceeded through the intersection at a speed of 15.3

TABLE 2.—TIME TAKEN BY AUTOMOBILES TO CLEAR INTERSECTION (12-FOOT SIDEWALK PLUS 36-FOOT ROADWAY)

Type of car	No. of observations	Time, in seconds	Speed, in miles per hour	EFFECTIVE HEADWAY		LANE CAPACITY (THEORETICAL)	
				Free movement, in seconds	Dense traffic, in seconds	Dense traffic	Free movement
Passenger:							
First car group	93	3.92	10.8	2.01	1.70	2 100	1 790
	161	2.77	15.3	1.43	1.20	3 000	2 500
Truck:							
First car group	21	4.61	10.9	2.78	2.44	1 475	1 300
	10	4.06	12.4	2.42	2.14	1 680	1 480
Mixed group	199	2.95	15.3	1.60	1.38	2 600	2 250

miles per hr in the case of passenger cars or a mixed group, and 12.4 miles per hr in the case of trucks. Using these speeds and the average spacing shown in Table 1, effective headways were computed under the conditions of reasonably free movement and of especially dense traffic. In these computations the length of a passenger automobile was taken as 14 ft and the length of a truck as 26 ft.

These data indicate that a single lane of a street in a congested district has a capacity of from 1 800 to 2 500 passenger cars per hr at an intersection, with interferences eliminated, and that reasonable speeds range from 11 to 15 miles per hr. The data also indicate that such a street has a capacity for trucks of from 1 300 to 1 500 vehicles per hr at speeds from 11 to 12.5 miles per hr. Where the traffic is mixed, as is usually the case, the capacity of a single lane is indicated to be approximately 2 250 vehicles per hr. Naturally, this capacity will depend upon the proportion of trucks and other vehicles present. The data further indicate that where traffic is especially dense, even higher values than the foregoing may be obtained. It is not likely, however, that these especially dense conditions could be maintained over a considerable period of time.

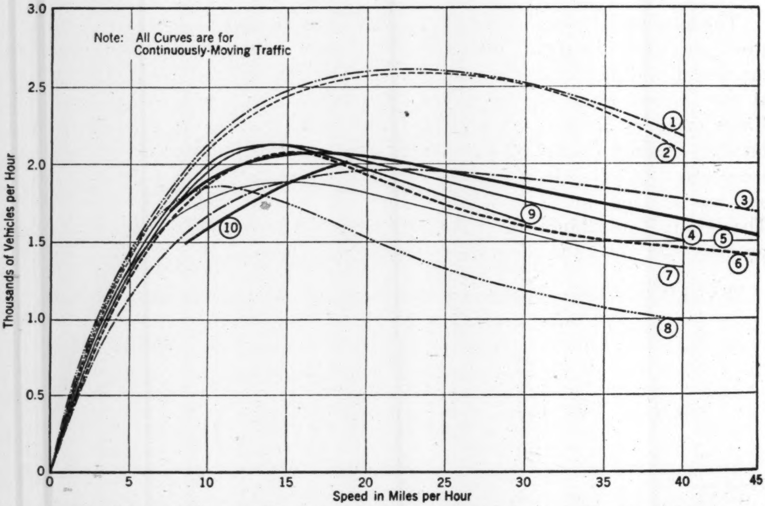

FIG. 1.—MAXIMUM HOURLY CAPACITY OF A SINGLE TRAFFIC LANE AT DIFFERENT SPEEDS

Some verification of these data was obtained from a group of curves (Fig. 1) obtained from various sources, which represent maximum hourly capacity of a single traffic lane at varying speeds. These curves show a range of hourly capacity of from 1 700 to 2 300 vehicles at 11 miles per hr, and from 1 900 to 2 500 vehicles at 15 miles per hr. Referring to Fig. 1, Curves 1, 4, and 9, respectively, are for Los Angeles, Calif., Detroit, Mich., and Norristown, Pa.[3]

---

[3] "A Study of the Traffic Problem," by William S. Canning, 1928, p. 16. The curve for Los Angeles (Curve 1) is shown in more detail in *Traffic Bulletin No. 143*, Am. Gas Accumulator Co., Elizabeth, N. J.

Curve 2, originally, was plotted from computations made on the basis of field data referring to the spacing of vehicles at various speeds both on crowded and on high-speed thoroughfares.[4] It applies to a continuously moving lane of traffic, on the assumption that the average length of vehicle is 14 ft. Curve 3 was plotted from data observed by the Pennsylvania State Highway Department. This curve is intended to show the "theoretical maximum capacity of one traffic lane under ideal conditions."[5] The sources of the data, study conditions, assumptions, etc., from which the computations were made, are not available.

Curve 5, Fig. 1, was derived and plotted by the Bureau of Traffic Planning, City of Pittsburgh, and represents the mean average of the nine remaining curves in this drawing. A blueprint of Curve 6, with its formula, supplied by N. W. Dougherty, M. Am. Soc. C. E., was the only item of reference material available for this curve. Evidently, it applies to continuously moving traffic, assuming all cars with four-wheel brakes, and, being derived from an equation, is theoretical.

Curve 7 is intended for an "uninterrupted traffic lane."[6] It was derived from a formula, the factors of which were obtained from actual field data and observations. Mr. H. S. Swan,[7] who is the authority for Curve 8, makes no mention of study conditions, how data were obtained, etc., except that "safe braking distance" is assumed and that no time is allowed for the application of brakes. Two other curves presented by Mr. Swan (not included in Fig. 1) are computed on different assumptions. Finally, Curve 10 was plotted by the Pittsburgh Bureau of Traffic Planning, based on studies of down-town Pittsburgh. This curve is theoretical, representing the flow of traffic, for a full hour, moving in a flexible, progressive, signal system.

Further light on the accuracy of Fig. 1 was obtained from studies of the vehicle flow on the Wilmot Street Bridge, in Pittsburgh (see Table 3). This is a two-lane bridge—one lane in each direction. It has a large reservoir at one end for entering vehicles to accumulate, and at the other end for leaving vehicles to spread out promptly, so as not to delay those on the single lane of movement on the bridge. Table 3 shows an average rate of 1 710 vehicles per hr at a speed of 20 miles per hr, which rate was sustained over a period of 5 min at a time. A rate of 1 680 vehicles per hr was sustained for as long as 25 min.

Further supporting data (Curve 10 of Fig. 1) were obtained based upon a number of studies in down-town Pittsburgh, principally on Second Avenue, where dense groups of traffic were observed moving through the progressive traffic signal system. These data indicate a movement of 1 700 vehicles per hr at a speed of 11 miles per hr, and 1 900 vehicles per hr at a speed of 15 miles per hr. Fig. 2 is a comparison of Curves 7 and 10 in Fig. 1. Both curves are on the basis of a cycle of 53 sec and a lane-moving, or "Go" time of 45.3% of the cycle, or 24 sec. It is to be noted that, at the points of greatest divergence of the two, Curve 10 differs from Curve 7 by only 15% at 12 miles per hr and 19% at 17 miles per hr. These data give substantial ground for the traffic capacity of a single lane of a street in a congested district as 2 000 to 2 500 passenger cars per hr with speeds of movement of from 11 to 15 miles per hr.

[7] "Theoretical Capacity of Roadways," by H. S. Swan, *Traffic Bulletin No. 142*, Am. Gas Accumulator Co., Elizabeth, N. J.

TABLE 3.—VEHICLE FLOW ON WILMOT STREET BRIDGE, PITTSBURGH, PA. (ONE LANE)

Date (1933)	No. of vehicles in 25 minutes	No. of vehicles in a maximum 5 minutes	Rate of flow, in vehicles per hour	Speed, in miles per hour
October 5	701	145	1 740	20
October 6	619	142	1 680	20
Average	143.5	143.5	1 710	20

Of course, these capacities are not actually obtained for all lanes, or even for the critical lane. Counts of actual traffic volumes and the hourly rate per lane for several typical congested Pittsburgh streets (Table 4), show a range of from 132 cars per hr to 754 cars per hr per lane. The highest rate (754 cars per hr per lane) was obtained on the Boulevard of the Allies at Grant Street, which is a viaduct approach to the congested district. The next highest rate of 508 was obtained on a bridge approach. At both these locations many of the usual interferences were not present, and there was constant pressure on the intersection from a long reservoir of automobiles waiting to get through.

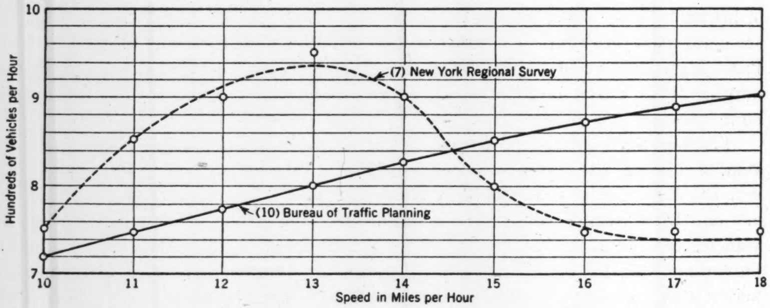

FIG. 2.—COMPARISON OF LANE CAPACITY DATA

The reason for this startling difference between capacities and actual flow is interference of one kind or another. Experience has shown that considerable interference can be eliminated, or at least reduced. Four types are recognized: (1) Cross-interference; (2) marginal interference; (3) internal interference; and (4) medial or center-line interference.

Interference by cross-traffic is the most obvious. It is evident that traffic from the main streets must stop while traffic on the cross-streets is moving.

If both the main street and the cross-street are given an equal proportion of the available time, it is obvious that the flow on each cannot be more than 50% of the capacity. Although this interference by cross-traffic can only be eliminated entirely by complete grade separation, it can be reduced by accurate proportioning of signal timing so that each street is given its proper share, but no more and no less than its proper share, of the available time. This proportion will vary throughout the day, but study indicates that the variation occurs with reasonable regularity, both as to time of the day, day of the week, and season of the year. Naturally, the facts concerning these variations must be obtained if the street is to be used at its maximum efficiency.

TABLE 4.—TRAFFIC VOLUME PER LANE, TYPICAL PITTSBURGH INTERSECTIONS

Street	At:	Traffic from:	Volume maximum, in 15 minutes	No. of lanes	Traffic per lane	Hourly rate per lane	Remarks
Fifth Avenue	Smithfield Street	East	124	2	62	248	Street cars
Fifth Avenue	Smithfield Street	West	195	2	98	392	Street cars
Ninth Street	Liberty Street	North	173	2	86	346	Street cars
Sixth Avenue	Grant Street	East	261	2	130	520	Street cars
Sixth Street	Penn Avenue	North	135	2	67	270	Street cars
Allies*	Grant Street	East	377	2	188	754	No street cars
Allies*	Grant Street	West	305	3	102	408	No street cars
Grant Street	Allies*	North	217	3	72	288	Street cars
Grant Street	Allies*	South	169	3	56	224	Street cars
Grant Street	Seventh Street	North	207	3	69	276	No street cars
Grant Street	Seventh Street	South	252	3	84	336	Street cars
Seventh Avenue	Grant Street	East	233	3	78	312	No street cars
Seventh Avenue	Grant Street	West	241	3	80	320	Street cars
Fourth Avenue	Smithfield Street	West	100	3	33	132	One-way†
Smithfield Street	Water Street	South	254	2	127	508	Bridge
Penn Avenue	Sixth Street	East	185	4	46	185	One-way
Smithfield Street	Fourth Avenue	South	196	4	49	196	One-way
Smithfield Street	Fifth Avenue	South	205	4	51	205	One-way

* Boulevard of the Allies. † Three lanes.

Cross-interference shows further restrictive effect in the delay that follows the stopping of a vehicle. Some data showing the time taken to start automobiles at an intersection, after the "Go" signal has been given, have been obtained as follows:

Position of car in line	No. of observations	Average time, in seconds
First car	224	1.6
Second car	224	2.9
Third car	202	4.1
Fourth car	185	5.1
Fifth car	101	7.4
Sixth car	81	7.6

The average time required to start equals approximately 1.41 times the position of the car in line. Naturally, the more stops that are caused by intersections which are too close together, the more frequently will this delay occur and the greater will be its effect in reducing street capacity. One of the fundamentals of good traffic regulation is to keep the traffic moving. The following simple illustration, involving the sixth and last car of a line stopped at an intersection, will show the importance of effective headway.

Assume the six cars to be stopped with a distance of 3 ft between each car, and each car to be 14 ft long. The rear of the sixth car will be 99 ft from the intersection, and must travel 147 ft for the rear of the car to clear the far curb of a 36-ft roadway. The data in Table 2 demonstrate that the first passenger car of a group will travel 48 ft in 3.92 sec and that the following cars of this group will travel 48 ft in 2.77 sec. The speed of the first car in traveling 48 ft was 10.8 miles per hr and that of following cars, as they cleared the intersection, 15.3 miles per hr. Assuming the average of these two speeds as the speed which the sixth car made in the remaining 51 ft which it was required to travel, gives a total of 17 sec before this sixth car clears the intersection, or an effective headway for these 6 cars of 2.82 sec, and a rate of flow of 1 275 cars per hr per lane. This is a reduction in lane capacity of 35 to 50 per cent.

Expressed in tabular form:

Description	Time required, in seconds
For sixth car to start	7.6
To travel 48 ft, at 10.8 miles per hr, after starting	3.92
To travel 48 ft, at 15.3 miles per hr, through the intersection	2.77
To travel another 51 ft, at 13.0 miles per hr	2.67
Total time	16.96
Effective headway	2.82

If intersections are close together there is no opportunity for vehicles to have sufficient free running time at higher speeds to overcome this delay, and the capacity of the street is permanently reduced.

A second cross-interference of considerable magnitude is caused by pedestrians who cross against the traffic. The degree of this interference depends upon the degree to which pedestrians obey the signals. Some data taken at typical intersections in the down-town district in Pittsburgh show that 56% of the pedestrians confronted by a "red" signal, failed to heed it, and crossed the street. The best obedience in the down-town district was at Smithfield Street and Sixth Avenue where 34% of the pedestrians confronted with a "red" signal crossed in the face of it. The corresponding value for Penn Avenue and Sixth Street was 71 per cent. An attempt was made to establish the relationship between pedestrian volumes, vehicle volumes, or turning volumes, and the degree of pedestrian observance of the traffic signals; but although a large volume of data was obtained, no consistent relationship could be determined.

In considering this pedestrian interference, it should be noted that no real effort to secure pedestrian control, except through educational means, has been attempted in Pittsburgh. Such interference, as well as that caused by pedestrians crossing in the middle of the block (commonly called "jaywalking"), has been reduced materially in a number of cities where real efforts have been made to enforce pedestrian regulations in congested districts. The value of such enforcement in increasing street capacity can be seen when it is realized that observations covering 4 hr for each of twelve intersections in down-town Pittsburgh showed that 22.9% of all pedestrians at the intersection crossed with interference of one sort or another. Naturally, the degree to which pedestrian interference reduces the street capacity depends on the volume of pedestrians present. Where such a large proportion crosses against the traffic the conclusion is inevitable that the street capacity has been materially reduced.

TABLE 5.—DELAYS CAUSED BY TURNS

* All left turns, except as indicated in Column (2). † Right turn. ‡ Actual speed.

Turns are a further type of cross-interference, particularly left turns. Factual data regarding the magnitude of such interference have been obtained.

These data, in Table 5, show: (*a*) The time required by vehicles of various types to clear their own lanes; (*b*) the delay to following traffic; (*c*) the time required to complete the turn; and, (*d*) the delay to oncoming traffic where the turn crosses such traffic.

Turns are designated by the number of the lane from which, and to which, the turn is made. Lanes are numbered across both streets starting from the corner about which the turn is made. Average delays to following traffic range from zero to 6.1 sec, depending on the type of turn, whether the streets are one-way or two-way, the type of vehicle, the volume of oncoming traffic, etc. Interference to oncoming traffic ranges to as high as 15.3 sec, and time to complete the turn to as much as 22.6 sec in the case of a street-car train making the ordinary left turn from one two-way, four-lane street to another. Table 5 shows that one passenger automobile, turning left from the center lane of a two-way, six-lane street, may delay following traffic in its own lane an amount equal to the time required for four such vehicles to go straight through; and that the street-car train making the turn previously described, occupies the time required for twenty-one passenger cars to move through one of the lanes in the opposite direction.

Of course, the actual reduction in capacity caused by these movements at any given intersection depends on the number of such turns per hour and the actual traffic volumes moving in both directions. The data can only be used in a practical manner when these volume data are known from actual traffic counts at the points being studied.

In considering these and other data presented in this paper, it should be borne in mind that they are presented merely with the idea of evaluating the various interferences in terms of their reduction of street capacity and so that the value of providing remedies for these interferences can be measured. The economic phase has not been discussed; for instance, it might be stressed, with considerable validity, that even if the left-turning street-car train mentioned did take as much time as is required for twenty-one passenger automobiles to move straight through, the street-car train actually carried twice as many passengers as all twenty-one of the passenger cars.

The time taken to make turns is further influenced by the volume of pedestrian traffic moving parallel with the traffic stream from which the turn has been made. Such pedestrian data should be available when studies are being made in connection with the gains to be expected from prospective turn eliminations.

In making turn elimination studies, the alternate routes, with the interferences likely to develop, must receive careful consideration. It should be accepted as a fundamental principle in such studies that two alternate routes must be available for each turn eliminated: One to the motorist before he reaches the point where the turn is to be eliminated; the other, after he has reached this point, in case he has forgotten to take the first alternate route. As far as possible turn eliminations should follow some reasonably regular pattern. It is extremely disconcerting and it adds to the confusion, for a motorist, especially a stranger, to find turns eliminated at random. This, also, is a factor in reducing street capacity. Properly located and legible signs are essential. An origin and destination study of the traffic involved in the turn is also extremely helpful in determining a proper course of action.

The second type of delay is caused by marginal interference, which is due to: (*a*) Vehicles entering and leaving parking lots and garages; (*b*) vehicles parked along the curb; (*c*) vehicles pulling out from the curb and backing in; and (*d*) the natural slowing down of moving cars in the lane adjacent to a line of parked cars, etc. Loading and unloading at the curb has a similar effect in reducing street capacity to parked cars. This interference is more difficult to correct because facilities for off-street loading and unloading have not yet been provided in most cities.

The reduction in traffic capacity due to parked cars pulling into, and out from, the curb is naturally dependent on the degree of turn-over in the parked cars. This depends on the type of district, the parking regulation, and the degree of enforcement secured.

In down-town Pittsburgh the average stopping time of all cars parked or loading on the streets is 21.5 min; 48% are loading and unloading, requiring 8.5 min; 24% are parked while the occupant is shopping, requiring 24.5 min; 28% are parked for 40.5 min while the occupant has gone to his work or is engaged in recreation. On the 1-hr parking streets, the average parking time is 37 min.

The effect of some of these factors can be illustrated by examining the ratio of lane use of two typical Pittsburgh thoroughfares, shown in Table 6. The first of these thoroughfares is Sixth Avenue, a four-lane, two-way street with a line of street cars moving in each direction. The data were obtained at the near side of each intersection.

TABLE 6.—RATIO OF LANE USE, TYPICAL STREET

Block	Intersection	Lane No. 1	Lane No. 2	Lane No. 3	Lane No. 4	Remarks
	Sixth Avenue at:					
1	Fifth Avenue	0.077	0.923	0.762	0.238	Parking garage next block
2	Wylie Avenue	0.499	0.501	0.715	0.285	No parking or stopping
3	Webster Avenue	0.499	0.501	0.715	0.285	No parking or stopping
4	Grant Street	0.506	0.494	0.650	0.350	No parking or stopping
5	Smithfield Street	0.239	0.761	.....	.....	Partial parking
6	Wood Street	0.070	0.930	0.798	0.202	Considerable parking
7	Liberty Avenue	0.580	0.420	.....	.....	No parking or stopping
	Fifth Avenue at:					
	Grant Street	0.133	0.867	0.728	0.272	....
	Smithfield Street	0.052	0.948	0.855	0.145	Parking in Lane No. 1
	Market Street	0.237	0.763	0.687	0.313	....

At Fifth Avenue, which may be called the entrance to Block 1, 0.077 of the traffic was in the curb lane whereas 0.923 was in the adjacent lane. The reason is plain when it is known that in the next block there is a large parking garage with a capacity of about 600 cars. Motorists simply will not use the curb lane when they know they will be blocked by cars entering and leaving this parking garage. In other words the capacity of the street has been reduced nearly one-half. In the next three blocks, where there is no such interference and where the no-parking regulation is strictly enforced, there is a practically even distribution of traffic; in fact, in the third block the curb lane even carries slightly more traffic than the middle lane. The character of the business in the next block (Block 5, Table 6) is such that a certain amount of parking, or at least short-time stopping is permitted. The curb-lane use drops to 0.239. In the next block (Block 6) even more parking and stopping is permitted, and the curb-lane use drops to 0.070. The next block (Block 7) is a short one with parking again absolutely banned; the curb-lane use increases to 0.580. In the latter block, however, some influence is felt from the fact that considerable of the traffic turns to the right. As far as the law is concerned, a no-parking regulation is "on the books" for this entire side of Sixth Avenue, but the business use and degree of enforcement are different.

The second street that will be examined—Fifth Avenue—is one of the main streets in the down-town district. The parking ordinance calls for "no parking at any time" for all the blocks in question, on both sides of the street. In spite of this regulation, the fact remains that considerably more parking is permitted on one side than the other. On the north side, where this parking exists, the ratio of curb-lane use is 0.052 whereas, on the other side, it is 0.272.

Some factual data regarding the actual delays to traffic in the adjacent lane caused by cars pulling into, and out from, the curb have been obtained. Each car which pulls out from the curb interrupts the adjacent lane for an average of 11.25 sec, whereas each car backing into a parking space interrupts the adjacent lane 16 sec. The total number of observations for cars leaving as well as entering was sixteen. The more frequent the turn-over the more serious is this effect in reducing street capacity. It must be remembered, however, that since the time necessarily allowed for cross-traffic to move has already had its effect in reducing capacity, some time is available between blocks for delays such as these, without their complete effect showing on the over-all capacity of the street. There is also a speed-reducing effect on the lane immediately adjacent to the parking lane. Its capacity is reduced as compared to a lane not immediately adjacent to a parking lane.

The third type of delay is caused by internal interference, such as the weaving of cars from one lane to another, the conflicts that occur when cars pass each other in adjacent lanes when the lanes themselves are too narrow, the effect of vehicles of different characteristics, etc.

Formerly, the width of roadways was determined by the old three-fifths rule. This rule determined the width as three-fifths of the distance between property lines, which distance itself had been somewhat arbitrarily determined —usually being some multiple of ten. Thus, for a 30-ft street, the roadway was 18 ft wide; for a 40-ft street, 22 ft, etc. Such widths permitted no similarity in the actual lane widths available for moving traffic. In few cities has any one attempted to make the actual lane widths available for traffic movement, suitable for such movement, by adjusting the sidewalk width. Furthermore, in the establishment of parking regulations scant consideration has been given to the width of the roadway, so as to provide for a given number of lanes of adequate width, for moving traffic. In some cases an 8-ft lane is available, in others, 9 ft, and, in others, 10 ft. A lane that is too wide is economically wasteful from the standpoint of pavement cost; a lane that is too narrow inevitably decreases the capacity of the street.

The traffic flow on a city street is not directly proportional to the number of lanes. Arthur N. Johnson,[8] M. Am. Soc. C. E., has demonstrated that, for rural highways, three lanes had twice the capacity, and four lanes, three times the capacity, of two-lane roads, etc. The same effect is not so evident on city streets. In down-town Pittsburgh there are a number of four-lane streets that are actually carrying more traffic than other six-lane streets with about the same apparent congestion. The difference is in the interference factors, which are variable from street to street.

Rough pavements limit street capacity, as do steep grades. Grades of less than 5% have little effect on modern traffic, however. Poor street illumination has its effect on traffic speeds, with a consequent effect in reducing capacity in districts where street use is heavy after dark.

Where routings are such that traffic must weave from one lane to another in order to move into the proper position for a turn, another factor which reduces traffic capacity is introduced, especially where the weaving must take place across several lanes. Some brief studies on this subject, applicable to down-town Pittsburgh conditions, were made on one down-town street (Second Avenue). These studies cover the weaving from one lane to a second lane (not multiple-lane weaving across several lanes). The studies were made in the evening peak period.

The method of the study may be briefly stated as follows: A measured course was laid out on Second Avenue, between Smithfield and Grant Streets, on the side for eastbound traffic. Several automobiles were hired, and drivers were instructed to weave from the lane nearest the center of the street to the next lane to the right, starting always at the first line of the measured stretch. The distance in which the weave was made and the speeds of the weaving vehicle were recorded. The speeds of following vehicles on both lanes were also recorded, as well as the speed of traffic when there was no weaving. Other observers checked the volume of traffic per lane in given time periods, so that the density of the traffic through which the test automobiles did their weaving was determined (see Table 7).

The composite average of these data shows a reduction of approximately 40% in the speed of traffic in the lane from which the weaving started, and a reduction of more than 30% in the speed of traffic in the lane to which the weaving vehicle moved. The average delay to vehicles in the lane from which the weaving started was 0.75 sec, and 2.6 sec in the lane to which the weaving vehicle moved. The range of weaving delays was from a negligible time to 9 sec. Translated into terms of effective headway, each weaving vehicle displaced from one to six vehicles moving straight through, the over-all reduction in capacity of the street depending on the number of weaving vehicles. Weaving, therefore, is another interference factor to be avoided if a street is to attain its maximum capacity.

Other elements that reduce the effective width of traffic lanes are structures such as loading zones and safety islands for street cars. Wherever possible the width taken out of traffic lanes by such structures should be compensated by cutting back the sidewalk opposite them a similar or greater distance. Even so, the necessary diversion of the traffic from a straight line is certain to reduce the over-all capacity of the street. Pillars of elevated railways are similar obstructions for which compensation should be made. On the other hand, structures such as loading zones for street cars introduce a helpful factor in that they permit traffic to move past street cars which are stopped to take on passengers.

* Lane No. 3 is next to the middle of the street.

Another factor in internal interference is based on the character of the vehicles themselves. Taxicabs are a delaying factor, not so much because the vehicles are incapable of moving with the traffic stream, but because the drivers lag in their effort to pick up passengers, or to get into desirable taxi stands. If cruising is prevalent, the extra volume of traffic added to the street displaces vehicles of other types. For fifteen intersections selected at random in downtown Pittsburgh, taxicabs comprised more than 8.5% of the total motor-vehicle traffic and in one block (Fifth Avenue, between Smithfield and Wood Streets) taxicabs comprised 25.8% of the total motor-vehicle traffic. In four other blocks they exceeded 10% of the total. Of the 4 591 cabs counted in this study, 76.7% were empty.

In another study (Table 8) covering 856 cabs and three intersections, 84% of the cabs were empty. The first appearance of a cruising taxicab was considered legitimate and, therefore, this vehicle was not included in Column (6), which includes only the second and subsequent appearance of each cab. During a 30-min period cabs were observed to enter an intersection two or more times as follows:

TABLE 8.—STUDY OF TAXICAB CRUISING

Time of observation (1)	Location (2)	No. of observations (3)	Percentage of Observations: Loaded (4)	Empty (5)	Cruising (6)

2	80	6	2
3	32	7	1
4	6	9	1
5	6		

Even granting that the first appearance of an empty cab was legitimate on the assumption that it was going to a call or a stand, 25% of the empty cabs were cruising; that is, they appeared, empty, two or more times at the same location within 30 min. Taxicab stands themselves furnish the same type of interference as parked cars. Such stands, of course, should never be permitted, except on streets where other vehicles are permitted to park.

Buses are also a delaying influence, in that they usually stop at the curb to pick up passengers and as a consequence delay the following traffic. One item receiving considerable attention is whether the bus stop should be on the near side, or on the far side of the intersection. Practice varies in different cities, although the prevailing practice seems to be to have the stop on the near side of the intersection so that stops necessary on account of the red light can be utilized for picking up passengers. On the other hand, when the bus arrives on the green light, such stops delay following traffic, which otherwise would go on through. Physical characteristics, such as the width of the street, number of lanes for moving traffic, whether parking is permitted or not, whether the street is flowing nearly to capacity, the number of right turns made into the street, etc., are determining factors in any individual case, although the practice must be made uniform throughout the congested district.

The effect of trucks and other commercial vehicles has been indicated previously. Due to their slower speeds they reduce the capacity of any thoroughfare. For instance, a traffic load of one-third trucks reduces the capacity about 20% as compared to a flow consisting entirely of passenger cars. Wherever possible, trucks should be segregated on certain streets. Trucks following regular routes to established terminals should be carefully considered and their route established so as to cause the least possible interference.

Because of their fixed use of the street-car lane, street cars limit following traffic in congested districts to the speed that these vehicles themselves are able to maintain, and thus lower street capacity. Many cities are using antiquated types of cars with not only slow speeds, but also slow accelerations.

The modern, high-speed street car developed by the President's Conference of the American Transit Association has an acceleration and speed enabling it to hold its own with motor traffic in the traffic stream, with the exception of the necessary stops to pick up and discharge passengers. This new car is being introduced in a number of cities. Of necessity, when the car stops to take on passengers, it blocks its own lane. Careful signal planning and study of the

characteristics of individual stops will enable the stopping and loading of street cars on the "red" signal, to a surprisingly large degree, thus eliminating much of this delay. Loading zones permitting the by-passing of motor traffic are a further help.

Some observations of results actually obtained in this respect at four rather heavy loading points selected at random in down-town Pittsburgh are presented in Table 9. At two of these points, loading platforms which permit the by-passing of other traffic, have been installed; at the other two, all automobile traffic must stop while the street car is loading. The readings were made during the evening peak from 4:30 P.M. to 6:00 P.M., and a total of 281 street cars was observed. The average "stop" time for the four points was 49.5% of the total time.

These data show that (see Column (6), Table 9): (1) 63.3% of the total loading time occurred on "stop" time; (2) 38.8% of the cars loaded exclusively on the "stop" time, and only 16.0% loaded exclusively on the "go" time; (3) some loading on the "go" time occurred in only 38.4% of the signal cycles; (4) 36.5% of the "go" time in the cycles in which cars loaded, was actually used for loading, and 47% of the "stop" time in the cycles in which cars loaded, was actually used for loading; and (5) 1.73 times as many seconds were used in loading on the "stop" time as on the "go" time.

A distinct difference was observed between the locations where loading platforms were installed, and those where patrons were required to board street cars without this protection. This difference illustrates not only the value of the loading platforms themselves, but the fact that the design of the signal system had actually taken this difference in street-car loading procedure into consideration. At the two locations without loading platforms (Columns (2) and (3), Table 9), the percentage of total loading time occurring on "stop" was 82.3 and 59.8 respectively; at the two locations with such platforms (Columns (4) and (5), Table 9) the corresponding percentages were 45.5 and 57.2, because it was not so important to have cars load on "stop" in the latter case. At the locations without the platforms, street cars loading exclusively on the green light were zero and 5%; at the locations with platforms these values were 44.9 and 12.5 per cent. Furthermore, the ratio of the seconds of loading on "stop," to the seconds of loading on "go," was 4.64 and 1.49 where there were no loading platforms, but 0.84 and 1.33 where there were loading platforms.

In discussing the effect of taxicabs on street capacity, the writer mentioned the fact that, in so far as considerable of this traffic was probably not serving a useful purpose, it was occupying the space that could be occupied by other vehicles, thereby reducing the street capacity to useful traffic.

In most congested districts there is another type of traffic, present in even greater volume, that is reducing street capacity in the same manner. This is through traffic, as contrasted to the strictly local, business-producing traffic.

In down-town Pittsburgh 49.7% of the vehicles entering between the hours of 6:00 A.M. and 12:00 midnight remained in the district less than 20 min and left by a different route from that by which they entered. The volume of this through traffic is illustrated by Fig. 3. In the evening peak period from 4:00 P.M. to 6:00 P.M., it amounted to 53.3 per cent. Progress through restriction

FIG. 3.—THROUGH TRAFFIC FLOW, CENTRAL BUSINESS DISTRICT, PITTSBURGH, PA.

of parking, elimination of turns, the creation of one-way streets, more efficient traffic signal systems, etc., cannot be continued indefinitely.

Traffic that merely passes through congested districts on its journey from one outlying district to another, adds nothing to the prosperity of a congested area. The tremendous relief from congestion which would result from the elimination of 40% to 50% of the present traffic is evident. What a rejuvenation business organizations could experience through the removal of that 40% to 50% of non-business producing traffic and its replacement by an equal volume of business-producing traffic! Such a change would not entail any greater burden on the streets of Pittsburgh than at present, and could be accomplished by the construction of a close in by-pass system around the congested district. It is essential if permanent traffic relief is to be secured. In the meantime some improvement could be accomplished by establishing, and thoroughly marking, preferred through routes over existing streets. Normally, through traffic filters to a considerable extent from one street to another in down-town areas, producing unnecessary confusion. A preferred route will often shunt this traffic flow to an adequate street hitherto neglected.

The fourth type of delay is due to medial or center-line interference. This is the interference that occurs between traffic moving in opposite directions. On radial, by-pass, and distribution streets, as well as on the open highway, where such highways approach large centers of population, it can best be eliminated by the use of a divided roadway with a center strip 15 to 30 ft wide separating the roadways used by traffic moving in opposite directions. Such a construction is largely impractical in congested districts. It is fortunate, therefore, that in such districts this type of interference is at a minimum and may be neglected, in view of the large amount of interference of other types.

CONCLUSIONS

On the basis of data presented herein, the following conclusions can be advanced:

(1) The traffic capacity of a single lane of a street in a congested city district, with interferences eliminated, is from 2 000 to 2 500 passenger automobiles per hr.

(2) Interference by cross-traffic at grade inevitably reduces the capacity of any street approximately 50 per cent.

(3) The stopping of a lane of traffic reduces the capacity of that lane 35% to 50% when the stops occur close together.

(4) In the absence of pedestrian control, as much as 23% of the pedestrian traffic crossing the street will interfere with vehicles, thus reducing the street capacity. As many as 56% of the pedestrians crossing the street in congested districts cross against the traffic. Crossing in the middle of the block or "jay-walking" is also prevalent. These practices, which reduce street capacity, can be greatly reduced with adequate pedestrian control.

(5) On the average, a passenger automobile turning left may delay following traffic a length of time equal to that required for four such vehicles to go straight through; a street car and trailer turning left may delay following traffic a length

of time equal to that required for twenty-one passenger automobiles to go straight through.

(6) A large parking lot or garage with the entrance on a main thoroughfare may have the effect of reducing the capacity of that street from 20% to 40% of the traffic which would otherwise use it. The extent of the reduction depends on the number of lanes of moving traffic on the street.

(7) The effect of curb parking is to reduce the traffic capacity of the street in question to 50% of the traffic that could otherwise use it.

(8) The traffic flow of city streets is not proportional to the number of lanes. City streets in congested districts do not follow the same rules in this regard as rural highways because of considerable variation in interference factors from street to street.

(9) Where street-car loading platforms, safety islands, elevated railway pillars, etc., obstruct the roadway, the curb should be "cut back" a distance at least equal to the width taken out of the roadway by such structures, to avoid any reduction in lane widths.

(10) One automobile weaving from one lane to another causes a change in effective headway equivalent to six vehicles moving straight through.

(11) Empty taxicabs, to a considerable extent cruising, may comprise as much as 20% of the motor-vehicle traffic on a street. To the extent that they are not serving a useful purpose and are occupying the space that could be occupied by other motor vehicles, they are reducing street capacity.

(12) Trucks reduce the capacity of a street 25% to 40% as compared to passenger automobiles. With trucks equal to approximately one-third of the traffic, the reduction in capacity is approximately 20% as compared to all passenger automobiles.

(13) Antiquated types of street cars reduce street capacity through slow speeds and slow accelerations. Modern street cars are available which can hold their own in the traffic stream. Street cars delay following traffic when they stop to take on passengers. Through the use of loading platforms and careful traffic signal system design considerable of this apparent reduction in capacity can be eliminated.

(14) As much as 50% of the traffic in congested districts is non-business producing, through traffic. This must be largely eliminated by the construction of convenient by-passes, if permanent traffic relief is to be secured. Improvement in this direction can usually be accomplished by establishing and thoroughly marking preferred through routes over existing streets.

ACKNOWLEDGMENT

The data on which this paper is based were obtained while the writer was Technical Adviser, and later Chief Engineer, of the Bureau of Traffic Planning of the City of Pittsburgh. He wishes to acknowledge with grateful appreciation the courtesy of Donald M. McNeil, Assoc. M. Am. Soc. C. E., Traffic Engineer of the City of Pittsburgh, for making the records of the Bureau of Traffic Planning completely available for the preparation of this paper as well as for his assistance in securing certain supplemental data.

REMEDIES TO RELIEVE TRAFFIC CONGESTION

By Donald M. McNeil,[9] Assoc. M. Am. Soc. C. E.

Synopsis

Growth of the automobile has resulted in congestion in business districts where the street system has not been expanded to compensate for this growth. Traffic interference, both pedestrian and vehicular, causing delays is discussed, and remedies are suggested. From an engineering standpoint most delays can be eliminated, but all improvements should be weighed from the standpoint of cost *versus* benefit to business. Inexpensive suggestions are given in the paper for relieving cross, marginal, internal, and medial interference.

Introduction

With rapid development of the automobile, practically every city has been confronted with serious congestion in its business section. This congestion, which can be defined as an over-crowded condition causing a decided reduction in the rate of speed of the movement of traffic, unquestionably reflects on the volume of business in the area. The development of the automobile has been so rapid that municipalities have been unable to devise regulations and develop improvements fast enough to cope with the situation. Re-arrangement of the existing street systems is decidedly expensive and, in many cases, from a financial and economic standpoint it is impossible; and the engineer is faced with the problem of examining the existing street systems to determine whether the ultimate capacity is now being obtained, and if not, to develop methods for obtaining greater capacity.

When the area of the main business section of Pittsburgh, Pa., is considered as 0.54 sq mile, comprising 14.9 miles of streets, on which, at present (1937), 75 000 vehicles enter daily; and when one considers the necessity of moving 19 127 vehicles, plus 541 street cars, in the peak hours, during which period approximately 100 000 persons use the various modes of transportation, a series of delays becomes extremely costly. The time required for automobiles to depart from the down-town area is five times greater, and, for street cars, three times greater, than on a thoroughfare on which there are no delays. The present average time required to depart from the down-town area is approximately 20 min. This average is three times greater than that which would be required on a street system with no delays. Reducing this to man-hour delays at the current rate of day labor (40 cts per hr), the cost of delays in Pittsburgh during only the peak hours of one day equals $10 000, not to mention the cost of the accidents which always accompany such delays. Therefore, it is easy to appreciate the exorbitant loss with which each municipality is faced under present street systems. The analysis for the peak period in Pittsburgh is more or less general in all cities.

---

[9] Traffic Engr., City of Pittsburgh, Pittsburgh, Pa.

It would be unreasonable to expect a street system improved so as to avoid all delays, because of the tremendous cost involved. However, many of the delays that are now causing congestion in cities of the United States can be eliminated, and the capacity of their street systems can be increased; but it is essential that, in each case, the benefits to be gained shall be weighed carefully against the cost of such improvements (which improvements can be decidedly expensive), and careful decision must be made as to which solution is warranted.

Where the expression, "speed," is used in this paper, it must be kept in mind that the prevailing average gross speed in a business section varies between approximately 5 and 10 miles per hr. From studies made on the relation between the capacity of a lane and speed, it was shown that capacity varied approximately in direct proportion to a speed of about 23 miles per hr, but for greater speeds, the capacity decreased as the speed increased. This condition is due to the difference in headway because of the distance required to stop a vehicle in case of an emergency. Therefore, when reference is made to speed in this paper, unless otherwise noted, it relates to a value of less than 23 miles per hr—that critical speed of the volume graph. The various delays possible may be classified in four groups as follows:

(1) Cross-Interference: That interference to a stream of traffic moving in one direction crossing the path of another stream of traffic on the same plane.

(2) Marginal Interference: That type of interference which occurs between moving vehicles and other vehicles, persons, or objects alongside the outer edge of the roadway.

(3) Internal Interference: That type of interference which occurs between traffic units moving in the same direction in the same traffic area.

(4) Medial Interference: That interference between vehicles moving in opposite directions at, or near, the center of the roadway.

REMEDIES FOR DELAYS DUE TO CROSS-INTERFERENCE

To minimize cross-interference, the necessity of traffic in one direction to cross-traffic in another direction must either be eliminated, reduced, or regulated so that the traffic involved does not arrive at its point of conflict at the same time. In cross-interference, the delay encountered is the time lost due to the necessity of slowing down and, in many cases, stopping, and re-starting. At an intersection it can be eliminated completely by the construction of grade separations on the intersecting streets or, at a series of consecutive intersections, by an elevated roadway through that section of the town. Such grade separations are decidedly expensive, frequently requiring the acquisition of more land area. Theoretically, the average typical intersection reduces the capacity of the intersecting streets to 50%, not considering the delay due to slowing down, stopping, and re-starting, because when traffic is moving on one street, the traffic on the other street must wait.

The grade-separation intersection does not require a change in the speed of traffic traveling straight through it. However, a slightly reduced speed is required by that traffic traveling from one street to the other street, provided the streets have ramp connections. Such ramp connections should be designed so that drivers wishing to travel from one street to the other may do so by a right turn. This type of movement provides less delay to traffic using the street on which the vehicle is traveling. The ramps that connect the roadway to which the vehicle is traveling should preferably be designed so that only a right turn can be made. The "clover leaf" design is an example.

Cross-interference can be greatly reduced by signal control or other automatic devices, so that cross-traffic does not arrive at points of conflict at the same time. This is illustrated by the results of the flexible progressive traffic signal system installed in Pittsburgh in 1928. Prior to this time the streets of the city were seriously congested. Since the installation of the system (in which time there has been practically no physical change in the street system) the traffic volume has increased approximately 40%; yet the average speed of traffic in this section was practically the same in 1936 as it was in 1928. This success is due largely to the frequent modification of the signal timings at individual intersections and the co-ordination pattern that has been developed to provide progressive movement.

A study in 1934 of the action of approximately 1 000 000 pedestrians revealed the fact that 56% of the total number approached the intersection on the red signal, and one-half, or 28%, showed no regard for it. Of the pedestrians who disregarded the red signal, 22.9% interfered with traffic that had the right of way on the street the pedestrian was crossing. These data show that a pedestrian interferes with the movement of street traffic on an average of one out of every fifteen times he crosses an intersection. This value was obtained on fixed time signals having a signal cycle of 50 sec. Further studies were made at these same intersections when the signal cycle was 60 sec, and the results were practically the same as those reported when the signals were operating at a 50-sec cycle. Delays due to this interference by pedestrians can be eliminated only by rigid enforcement, requiring the strict observance of the law prohibiting pedestrian movement during the red-signal period. In determining the proper length of the signal cycle, consideration should be given to the length of time that pedestrians are required to wait to cross the street. Studies made by Mr. J. Rowland Bibbins[10] indicate that the total violations of pedestrians crossing against traffic on a 20-sec red period would be perhaps only one-half that on a 30-sec red period, and the latter only about one-third that on a 60-sec red period. Although no data are available of the number of pedestrians crossing in the middle of the block, thus interfering with the movement of traffic, it is evident that delays from this cause are considerable. Records indicate that this jaywalking of pedestrians is decidedly dangerous and frequently causes accidents. The remedy for this type of delay is a rigid enforcement of the laws eliminating jaywalking and confining pedestrian crossings to the intersections.

When turning right or left at an intersection, a vehicle is required to cross through the pedestrian traffic crossing on the cross-walk of the throat of the street into which the vehicle is turning. No data are available to show the number of times such vehicles interfere with pedestrians. However, from studies of turn delays made in Pittsburgh at typical business intersections, it was found that each right-turning vehicle delayed through traffic, traveling in the lane from which the vehicle turned, an average of 0.7 sec; and that each left-turning vehicle delayed not only through traffic in the lane from which the vehicle turned, an average of 1.7 sec, but also delayed the traffic in the opposite direction an average of 2.6 sec. This excessive delay of 2.6 sec is due largely to the interference of pedestrians legally crossing the cross-walk of the throat into which the vehicle is turning. Some of the remedies for these turning delays are as follows:

---

[10] *Transaction*, National Safety Council, Annual Safety Congress, 1930, p. 126.

(*a*) If there are many turning vehicles, in a heavy pedestrian traffic, it is possible that the remedy may be the provision of a pedestrian interval in the signal sequence, during which period no vehicles shall move.

(*b*) If it is possible to sacrifice the flexibility of the intersection, the remedy could be the restriction of all turns, or of certain turns.

(*c*) If property can be obtained reasonably, it is possible that the remedy would be the construction of a circular arrangement, so that traffic desiring to turn left would proceed slightly beyond the intersection, turning right around a circle and waiting for the red light before completing the movement through the intersection. Such an arrangement would likewise interfere materially where there was heavy pedestrian movement, and would require the handling of the traffic twice through the intersection.

(*d*) It is possible that the remedy would be the construction of a circular roadway requiring all traffic to move in a rotary manner. This circle should be of ample diameter, preferably 250 ft, or more. Although it would eliminate cross-interference, it would create a weaving interference—to be described subsequently.

(*e*) Possibly, at least a partial remedy would be to construct connecting tunnels between basements of large stores located at the intersections.

(*f*) A possible remedy would be the provision of pedestrian under-passes where traffic would not permit turn eliminations, or the provision of a pedestrian interval. The experience with pedestrian under-passes on outlying main arteries in Pittsburgh has been extremely unsatisfactory, because of their little use. If pedestrian under-passes are provided, they should be extremely sanitary, well-lighted, designed to require the least possible exertion on the part of pedestrians walking through them, and preferably arranged to attract their use, such as with show windows and connections to buildings. Pedestrians should be educated as to their advantage.

In summarizing, the remedies for delays encountered by cross-interference are likely to be found in one or more of the following:

I.—Elimination of cross-interference due to pedestrians:

- (*A*) Rigid enforcement of pedestrian regulations: (1) No crossing on the red signal light; (2) no jaywalking.
- (*B*) Provision of a pedestrian interval, during which period no vehicles shall move, and on the other periods, no pedestrians shall move.

(*C*) Connecting the basements of large buildings by pedestrian tunnels. (Partial remedy.)
(*D*) Construction of pedestrian under-pass tunnels.

II.—Elimination of cross-interference due to vehicles:

(*A*) Provision of grade separation intersections or elevated roadways.
(*B*) Provision of a progressive co-ordinated signal system, or its equivalent.
(*C*) Elimination of turning by vehicles.
(*D*) Provision of a far-side, right-turn, circle roadway to replace left-turning movement.
(*E*) Provision of a circular roadway.
(*F*) "Channelize" wide uneven intersections.

REMEDIES FOR DELAYS DUE TO MARGINAL INTERFERENCE

Marginal interference is usually created by the granting of conveniences to a few at the expense of a majority. Its remedy in general is inexpensive and involves limiting these conveniences. The greater part of marginal interference is caused by street and off-street parking, and the loading and unloading of vehicles. Its entire elimination is impossible, as the Courts have ruled that a municipality cannot restrict a vehicle from stopping for that period of time necessary to load or unload a vehicle expeditiously. It is an admitted fact, substantiated by the Courts, that streets are primarily for the purpose of the moving vehicle. However, such a vehicle is decidedly limited if it cannot stop to discharge any of its occupants or materials. The necessity of permitting vehicles to stop for loading or unloading has resulted in a considerable restriction of the use of the curb lane. From lane-ratio data available, the curb-lane usage of a street on which there is a moderate loading or unloading traffic is less than one-half that of the center lane, whereas on other streets where there is considerable loading, the curb-lane usage becomes practically zero. Such delays due to loading and unloading can be eliminated by restricting all stopping of vehicles (at least during the rush periods), in which case, unless other interference is encountered the lane distribution ratio will be approximately equal, as indicated by other available data. This elimination of stopping has the possibility of providing an increase of 40% in the capacity of a four-lane street. Where parking is permitted on a street, it is found that there is generally no usage obtained from the curb lane. If this parking were prohibited, and if reasonable loading were permitted in the curb lane, it would be possible in some cases to increase the capacity of the street 50%; and, with the restriction of loading during the peak periods, it would be possible to increase the capacity of the street 100 per cent. This statement, of course, is made with the provision that the curb lane has ample width for moving vehicles and that the intersections are capable of handling this additional traffic.

In addition to the obstruction of the curb lane, the parked or loading vehicle interferes with free-moving traffic in the second lane by pulling in and out of the curb lane. The seriousness of this delay depends upon the number of vehicles loading and unloading, and the rate of turn-over of parked cars. It has been observed, particularly in the business section, that the traffic in the lane adjacent to parked vehicles proceeds at a lower rate of speed than it would have traveled had there been no parked vehicles present. This is due to the preparedness of the operator to be able to stop his vehicle in the event that a parked car suddenly pulls out from the curb lane, or a jaywalking pedestrian steps from between parked cars into the path of his vehicle. If parking were eliminated, there would be no cars to pull out from the curb lane, and the distance in advance that the operator would be able to see the jaywalking pedestrian would permit the vehicle to progress at a higher rate of speed. In January, 1928, the City of Chicago, Ill., put into effect a blanket "No Parking" ordinance in the Loop District. In comparing the data of 1926 with that of several years subsequent to the restriction of parking, it is found that, in spite of 18.3% increase in traffic, street-car speeds increased from 18% to 33%, and speeds of all traffic increased 15% to 40%; in addition, total accidents were reduced 10 per cent.

The delays caused by vehicles entering and leaving parking lots and garages is another form of marginal interference. Off-street parking facilities are essential in a business section, and as it becomes necessary to restrict more and more street parking, the off-street parking facilities will be increased. Their success depends largely upon their location and their entrances, and it is for this reason that proprietors endeavor to locate them centrally and with entrances on main thoroughfares. The location of entrances to parking lots or garages on a main artery is similar to the addition of an intersecting street and, unfortunately, these lots and garages receive and discharge their tenants during the peak periods of traffic movement. Efforts should be made to have entrances to parking lots and garages open on to streets having the least congestion, and preferably on to streets that do not have through-artery characteristics. These lots and garages should be designed with sufficient reservoir space and operated with a sufficient number of attendants, so that vehicles desiring to enter them will not be required to wait on the street or the sidewalk before admittance. The exits should be located so that vehicles can be discharged on to a secondary street and, by way of connecting streets, distribute themselves to their respective main arteries.

Remedies for Delays Due to Internal Interference

Internal interference, being the type that occurs between traffic units moving in the same direction in the same traffic area, is due in general to the difference in speeds of the various vehicles, the tendency of certain vehicles to foul the lane or lanes adjacent to that in which they are traveling, and any physical condition of the roadway that may change the speed at which the vehicle is traveling.

Many of the streets in the business sections were planned during those periods when traffic consisted largely of horse-drawn wagons, bicycles, and other slow moving vehicles, with the result that in many cases the lane widths are not adequate for the free movement of present-day traffic. Formerly, it was the practice in designing streets, to make the roadway itself three-fifths of the street width; thus, when the street was 30 ft wide, the roadway was made 18 ft wide; for a 40-ft street the roadway was made 24 ft wide, etc. From an analysis of such roadway widths it will be noted that there is no similarity in the actual lane widths for moving traffic. The current design of new roadways in a business section provides lane widths for moving traffic of 9 and 10 ft, preferably 10 ft, and sufficient sidewalk area for the future development of that section. Where the lane widths are not of proper width (at least 9 ft) the speed of traffic is reduced materially, and thus the capacity of the street is curtailed.

Pedestrian traffic has increased materially in business sections, and in many cases sidewalks are not adequate to accommodate pedestrians properly. Some cities have attempted to correct the roadway deficiency by encroaching on the sidewalk areas, with the result that in many cases pedestrian traffic has been penalized. One possible remedy for an over-crowded condition of both vehicles and pedestrians would be to elevate the sidewalks to provide more roadway area. This type of improvement, while decidedly less expensive than the construction of arcades in existing buildings, or the razing of buildings, places an inconvenience on pedestrian traffic, unless the plan is adopted for an entire area, as it requires the constant walking up and down to, or from, the upper sidewalk.

Many of the old street designs provided for such small curb radii at the intersections as 6, 8, and 10 ft, which required traffic that was turning right from and on to relatively narrow streets, to proceed at a slow rate of speed. Frequently, such traffic is obliged to encroach on the wrong side of the roadway in making the turn. In remedying this condition by enlarging the curb radii, the engineer must be careful that the curb is not made so inviting as to encourage an excessive rate of speed, thus subjecting pedestrians to a hazard. Where pedestrian traffic is relatively light and the speed of traffic is approximately 25 miles per hr, curb radii of 35 ft are preferable. Where pedestrian traffic is heavy, it is suggested that the curb radii be modified to 20 ft, which will permit a comfortable speed for passenger cars of 10 miles per hr, and in some cases as much as 15 miles per hr, and a somewhat slower speed for commercial vehicles having large turning requirements. Where the street paving is in poor condition, or where it is decidedly slippery for driving, the speed of traffic is considerably slower than traffic traveling on improved non-skid pavements. Street car rails also have a tendency to reduce the speed of traffic, because of the possibility of skidding during slippery periods. At night, the speed of traffic in busy areas that are congested, is somewhat governed by the degree of visibility afforded the driver. Where there is sufficient street lighting, whether by store windows or street lights, or a combination of both, so that the driver can readily see any object that may appear suddenly in his path, he is inclined to drive at a faster speed than at places where he must rely largely on the headlights of his vehicle.

Another form of internal interference is that caused by vehicles weaving from one lane to another. In order to permit flexibility of a street system, this weaving is essential in many cases. Frequently, however, vehicles weave from one lane to another, due either to the inattention of the driver, or to his desire to travel faster than the vehicle preceding him. In many cases, this unnecessary weaving can be eliminated by "channelizing" the roadway (that is, by establishing closed lanes), and requiring persons traveling in a given lane to confine themselves to it. Frequently, the marking of the street will help materially to guide motorists. In a preceding part of this paper, a suggested solution for cross-interference is to provide a rotary circle of proper diameter. The success of this type of a roadway is due to the elimination of cross-interference at the sacrifice of weaving interference. The number of arteries connecting the rotary circle and the movement of the traffic using the circle determines its capacity. Unfortunately, sufficient data are not available to determine the exact capacity of a circle; nor are there sufficient developments of a rotary circle from which to obtain data, due to the fact that of the circles in use to-day, their traffic movements, roadway design, diameters, etc., are different. From such data as the writer has been able to obtain, a circle having an island 250 ft in diameter and a roadway 50 ft wide, has a capacity of approximately 5 000 vehicles per hr. This capacity is considerably less than that of a grade separation of the "clover leaf" design, but considerably less expensive.

The success of any business area depends upon the facilities available to the business houses to receive and deliver their merchandise, which often requires the use of large trucks. In general, these trucks travel at a decidedly slow rate of speed, compared to passenger automobiles and street cars, and require more lane area when turning either right or left. In addition to the delays caused by the difference in speed, the trucks (unless properly provided for) again create serious delays when in the act of loading or unloading. The municipality should encourage all new buildings to provide all-street loading, as well as off-street parking facilities. It should provide places such as loading zones where these vehicles can pull into the curb to discharge or to pick up their loads, without stopping in the second lane. Establishments that are already developed and have not provided off-street loading facilities should be encouraged to confine their loading, if possible, to their alley or their secondary street exits. The municipality should reserve these alleys for such use by the restriction of parking because, not only do they provide the merchants with loading facilities, but they are important fire-protection factors for the buildings in the congested areas. It would not be practical to prohibit the use of streets in the congested area to commercial vehicles, because of the hardship it would inflict on the business establishments. It is possible, however (at least, at certain periods of the day) to restrict certain types of deliveries, such as coal, produce, etc.; and if such arrangement can be made with the express companies, that they endeavor to do most of their delivering prior to noon. From studies made by the Bureau of Traffic Planning Survey, in December, 1934, in Pittsburgh, 48% of the vehicles that stop at the curb are being loaded or unloaded with either passengers or merchandise, which indicates the demand for the aforementioned facilities.

The operation of taxicabs in the congested area creates another form of internal interference during the peak periods of the day. The taxicab, unless otherwise regulated, will travel at a slow rate of speed, because the driver hopes to have a pedestrian hail him for service. This is encouraged by the practice of taxicab companies that compute the wages of their drivers on a percentage basis of their day's receipts. Were the driver proceeding at the same rate of speed as the other vehicles, he is liable to lose this business, as he could not stop suddenly without the possibility of an accident to the vehicle traveling behind him; or he might not see the pedestrian signaling for him. A study of the operation of taxicabs in Pittsburgh showed that 26% were cruising (that is, they approached the same location empty twice or oftener within a 30-min period). The municipality may remedy this interference caused by cruising and slow moving taxicabs by requiring taxicab companies to provide adequate off-street parking facilities, and to see that ordinances be enforced rigidly. However, taxicabs are not the only vehicles that "cruise." Studies made at many intersections in the business district of Pittsburgh showed that in some cases 17% of the traffic on certain streets was cruising traffic (that is, traveling around the block either looking for a place to park, or looking for a person they were to meet, who happened to be late, etc.). To remedy the delay caused by the cruising passenger car is decidedly difficult. This problem has been solved in one or two cases in Pittsburgh by restricting the parking, which eliminates those vehicles looking for a place to park, or by restricting turns at the intersections where cruising is prevalent. These restrictions of turns and parking have made it so inconvenient for the person cruising that many have been discouraged in this practice, and have arranged to meet people in less congested areas.

At wide, uneven intersections having a large street area, where many of the vehicles weave and cross each other, the construction of islands and the "channelization" of the roadway confines the various movements to their proper lanes, and frequently eliminates many of the weaving and crossing delays that formerly existed at the old intersection, in addition to creating a safer condition for both vehicular and pedestrian traffic.

The co-ordination of signals enters into internal interference in that the time for starting and stopping the various types of vehicles differs materially. If the signals are co-ordinated so that the necessity for stopping and re-starting is minimized, many of these delays will be eliminated.

Probably the most serious type of internal interference is due to the loading and unloading of public carriers—the street car and the bus. With the modern improvement of these mass transportation vehicles and the recent development of the model street car, the delay due to different traveling speeds has been greatly reduced. The bus, when stopping to pick up or to discharge passengers, pulls over to the curb and obstructs the curb lane in the same manner as a parked car. The street car does not have the flexibility of being able to pull to the curb to pick up or to discharge its passengers, so that, in many cases, when in the act of loading or unloading, it obstructs not only the curb lane, but also the free lane in which the street car travels. If the adjacent area is controlled by a co-ordinated signal system, signals should be timed so that most of these mass transportation vehicles will arrive at their stops at that period of the signal sequence when traffic in their direction is stopped. That this is practicable is illustrated by the example in Pittsburgh, where it is possible, due to correct signal timing, to do 63.3% of the loading on the stop signals. Another remedy for delays in both lanes by street cars is the construction of street-car loading platforms, which permit vehicles between the loading platform and the curb to move during the time the street car is loading. There has been considerable agitation to pass legislation such that, if a common carrier arrives at an intersection during the green signal, it should not be permitted to stop to pick up or to discharge passengers, but must proceed to the next intersection. This is a drastic remedy and would create a decided hardship for the people who rely on the mass-transportation vehicles.

As previously stated, considerable internal interference has been due to the difference in the speeds of the various types of vehicles and the necessity for the mass transportation vehicles to stop frequently to pick up or to discharge passengers. A possible remedy for this interference is illustrated by the experience in Pittsburgh where two main adjacent thoroughfares, Smithfield Street and Wood Street, were restricted to one-way traffic, northbound and southbound, respectively. The effect was to restrict the parking of automobiles to the right-hand curb lane, and the slow-moving and mass-transportation vehicles to the lane adjacent to the parked vehicles. The success of this plan is illustrated by the lane-ratio data recorded at every intersection along these two main streets, which show that the extreme right lane has a usage of 2.5%, the lane adjacent to the parked vehicles, a usage of 24.5%, the next or third lane from the right, a usage of 60.5%, and the extreme left curb lane has a usage of 12.5 per cent. This indicates that the left half of the street carries 73% of the traffic, whereas the right half carries 27 per cent. If two-way traffic were permitted on these streets, there would be considerable request for permission to park on both sides of the street, and it is probable that street cars would operate in both directions on both streets. These data indicate that making these streets one-way has permitted an increase in capacity of 80% more than if they were operated on a two-way basis. This accomplishment was due to the provision of lanes for the faster moving vehicles; and it does not restrict the capacity of the streets to that of the slower moving vehicles. It is not practicable, however, to confine any street to one-way traffic. Study should be made of the origin and destination of the traffic using the streets, and the possibility of ready access to and from the various destinations. Unless such consideration is given, one-way streets are likely to cause an unnecessary distance of travel and the addition of turns to offset the acknowledged advantages.

Remedies for Delays Due to Medial Interference

The degree of medial interference is largely dependent on the lane widths of the roadways. Where the lanes of a street have a width of not less than 9 or 10 ft, there is little or no medial interference. As the lane width is reduced, vehicles traveling in opposite directions will proceed at slower rates of speed. Medial interference is created when faster moving vehicles desire to overtake and pass other vehicles by pulling around to the wrong side of the roadway. This type of interference can be eliminated readily by the construction of center strip islands, which have yet another advantage in that they can be designed to provide a "reservoir" off the roadway proper permitting vehicles to turn left without obstructing free-moving traffic. The effect of the center strip island is more to eliminate the hazard of accidents than to minimize delays of traffic. It is felt, in general, that such constructions are impracticable in congested districts, because of the additional valuable street area required—an area already limited in many cases. The delays due to medial interference are practically negligible where proper lane widths are available, and it is suggested that concentration be given to the other types of delays because of their seriousness.

OTHER REMEDIES FOR DELAYS

The preceding parts of this paper have dealt with the various types of interference that cause delays to motor traffic. As to the exact seriousness of these delays, little has been published except to evaluate it in terms of units. The relative seriousness is dependent upon the volume of traffic that is involved during certain periods; as this volume increases the congestion will decrease, and as it decreases, congestion will decrease correspondingly. The engineer is faced with the additional problem of analyzing the street system to determine, at no hardship to the inhabitants of the municipality, methods of decreasing the volume of traffic that must travel on the various streets and thus reduce existing congestion.

A possible remedy for reducing the volume of traffic during the peak period is to stagger the business hours. This solution has been discussed for many years and, in some cases, has been found impracticable because of the interlocking of the various types of businesses. It is doubted whether any sincere experiment has been made of the staggering of business hours, because of the habits of the American people and their desire to associate at common hours. For example, when production is necessary, factories and mills operate 24 hr per day; milk companies deliver milk in the early hours of the morning because the public demands fresh milk for breakfast; and meat packers, in order that their products shall not spoil, must deliver their loads before the sun is high. There is no difficulty in the operation of the milk companies or the meat packers, except that there has been a demand that has required the staggering of their business hours. As conditions become more critical and as the various industries realize their loss because of the congestion of traffic, they will undoubtedly favor changing their transportation schedules to more profitable hours. Such a solution of a whole-hearted staggering of business hours is possibly "far-fetched." However, it may be the ultimate solution that the American people must expect, in order to remedy their traffic "snarl." If such a plan were followed, the critical peak period, because of being distributed over several periods, would be materially reduced, and congestion would be correspondingly decreased.

Another possible means of decreasing the volume of traffic is to make a careful analysis and survey of the existing mass transportation system. During the ten years, 1927 to 1936, the private automobile (which carries merely an average of 1.8 persons) has transported about 50% more passengers into a business district than formerly, whereas the total number of passengers carried by mass-transportation vehicles has decreased. This has been due to a change in the mode of transportation of the general public from that of the original mass-transportation vehicle to the private automobile. This change has probably been due to the additional convenience afforded by the private automobile. The engineer of a municipality, whose duty it is to facilitate the movement of traffic safely, should strive to handle the largest number of people in the least number of vehicles. There is little question but that an individual, when driving his automobile to and from work and parking it in the congested area, spends several times the money that he would in using a mass-transportation vehicle. As the mass-transportation facilities are improved, there is little question but that the number of private automobiles in the congested area will be reduced, which will relieve the congestion and also decrease the demand for street and off-street parking spaces.

A survey should be made of the various routes of the surface common carriers: Their speeds, their points of loading and unloading, and the type of their service. There has been considerable controversy over the proper type of routing for surface carriers in a congested area. Three types have been advanced: "Short-looping," "through routing," and general routing. "Short-looping" consists in bringing the common carriers to the outskirts of the business area, discharging and picking up their passengers, and proceeding away from that section. In "through routing," the common carriers proceed straight through the business section, stopping to discharge and pick up passengers as required, and proceeding in the opposite direction from which they originated, to the end of the line, where they turn around and proceed back to town. General routing is the type most commonly practiced to-day. This is the routing of the common carriers through the business section, past the various large department stores, into the center of the section, and turning and proceeding back through the town. This type requires the carriers to make many turns, cross one another frequently, and travel practically a double distance in the congested area. There is no "hard and fast" solution for this condition of the private automobile vying with the surface common carrier. Some of the solutions advanced to the present day involve the construction of elevated lines and subways; and yet the city that does not have these facilities, and must rely entirely on surface common carriers, has a more critical problem. The engineer of a municipality should strive to improve mass transportation facilities, which in the end will decrease the use of the private automobile in the busy areas, and thus reduce congestion.

A third possible solution for reducing traffic volumes is to study and analyze street systems carefully to determine whether adequate by-pass facilities are available to avoid congested areas. From an origin and destination count made in Pittsburgh, indications are that 49.7% of the vehicles entering the business section between the hours of 6:00 A.M. and midnight, left by a different throat from that by which they entered, within a period of 20 min, which time was practically equal to that required to travel from the entry throat to the exit throat. This indicates that the vehicles did not stop in the business section, but, because of not having adequate by-pass facilities, were obliged to use the connection through the down-town section. From further analysis of these entering and leaving data, it is evident that not only does this through traffic hold consistently through the day, but that during the peak period from 4:00 P.M. to 6:00 P.M., 53.3% of the flow in the business section was through traffic, which, if eliminated, would materially relieve the congestion. This is a startling example to illustrate the relief of congestion that would be afforded the City of Pittsburgh if adequate by-passes were provided around the business district.

One should not be misled by this statement, to conclude that facilities are not available in Pittsburgh to enable the avoidance of the congested area, as there are several entry routes that can be used. However, these routes do not have the characteristics that would encourage motorists to use them in preference to the route through the business section. By-pass routes provided should be of a characteristic high-speed design, so as to minimize delays, and should be connected properly to all the entering and leaving arteries. Unless a by-pass has a high-speed characteristic and is attractive to motorists, it will be of little value, and will fail to serve the purpose for which it was created.

Prior to making the "origin and destination" count an engineer making the statement that 53.3% of the flow was through traffic would have been criticized, as it was felt to be an absurd value. Consequently, it is probable that this condition is present in other cities, even if highway officials feel that they have adequate routes for avoiding the business sections; but from a study such as the one cited, the engineer will determine whether these facilities are being used for the purpose intended, and if they are not being so used, an analysis of these by-pass routes should be made to eliminate the delays that are diverting traffic to the congested areas.

Another means of reducing delays falls within the jurisdiction of the police authorities. In preceding parts of this paper, there was discussion of possible restriction of parking, possible restriction of turns, regulation of pedestrian traffic, etc. After a careful study has been made and regulations have been recommended and enacted, it is necessary that they be enforced rigidly, and this is the province of the police. The engineer should be assured of the full co-operation of the police authorities on any regulations established. To enact a regulation does not fulfill the remedy for the delay in traffic; the removal of the vehicle causing the conflict is also required, and it is that conflicting vehicle that must be removed by the police officials.

A municipality should have highly trained police officers, deserving, and having, the respect of the motoring public. Such a staff will facilitate materially the movement of traffic and will be prepared to reduce congestion in the event of an emergency.

CONCLUSION

To relieve traffic congestion and increase the capacity of a street system is possible, as illustrated in several ways in this paper. Responsibility for the particular type of remedy to be devised is placed upon the traffic and city planning engineers. Their decisions must take many phases into account, such as the habits of the people, the demands of merchants, the cost of the proposed improvements, and the extent of the relief that is to be expected. In many cases, it has been found advantageous, in making such decisions, to temper the recommendations of the engineers by the opinions and suggestions of a group of citizens representing all classes of society, so that by providing an opportunity for every phase of business life to consider the problem, the best possible solution may be obtained. However, the engineers know the causes of congestion and the remedies for increasing the capacity of existing street systems, and any final decisions should be made with their guidance and advice.

IMPROVEMENTS TO REDUCE TRAFFIC ACCIDENTS

By Arnold H. Vey,[11] Esq.

Synopsis

Any detailed analysis of motor-vehicle accident reports discloses numerous conditions, circumstances, and situations involved in the problem of highway accidents. Consequently, hundreds of causes must be considered and, to complicate the problem further, these causes may operate either singly or in combination. Therefore, it is difficult to determine, with any degree of accuracy, the exact number of accidents that may be charged to the car, the highway, or the highway user. All three elements are involved, and they contribute in one way or another, and in varying degrees, to highway accidents; but the highway user (the driver and pedestrian) is responsible for the greatest number. In other words, most motor-vehicle accidents are caused by some improper action on the part of the person or persons involved, regardless of whether such action was wilful, or due to negligence or ignorance.

It seems reasonable, therefore, to suppose that if all highway users knew, and would voluntarily observe, safe highway practices at all times, the present-day accident problem would be materially lessened. Actually, however, the solution is not so simple. Because of human frailties and the impossibility of supervising and governing the actions of all persons at all times, safety on the highway is made extremely difficult. Educational endeavors and increased enforcement activities are not only essential but invariably prove helpful. However, such activities, despite their importance, are not in themselves a complete solution. It is necessary that roadway facilities be designed and applied which are inherently safe, as far as possible, in order to render the failures of human beings of lesser or little importance.

Roadway facilities, of course, are of many component parts, a number of which may be classed as major highway improvements. Time and space will not permit a discussion of all such improvements, and it is the purpose of the writer, therefore, to discuss only those about which accident facts are immediately available. As most major highway improvements during recent years have concerned State highways and, primarily, in rural or less densely populated areas, the scope of this paper is confined largely to improvements on the State Highway System of New Jersey.

Note.—Presented at the meeting of the Highway Division, New York, N. Y., January 21, 1937.

[11] State Traffic Engr., Div. of Traffic Control and Regulation, State Dept. of Motor Vehicles, Trenton, N. J.

In this connection, it is important and also of interest to have some knowledge of the accident problem as it exists in New Jersey and as it concerns New Jersey State Highways.

ACCIDENT EXPERIENCE IN 1934, NEW JERSEY STATE HIGHWAY SYSTEM

The data included herein are taken from reports of accidents filed by the motorists involved, together with supplemental reports from police and other officials concerned with motor-vehicle traffic and highway accidents. The reports include accidents involving death and personal injury, as well as those resulting in property damage to the extent of $25 or more.

Total Accidents.—Table 10(*a*) represents the number and severity of accidents in New Jersey during 1934. Of the total accidents, 3.5% involved fatalities, 55.9% involved personal injury, and the remaining 40.6% concerned property damage only; 7 217, or 21.4%, occurred on the State Highway System.

TABLE 10.—NUMBER AND SEVERITY OF ACCIDENTS IN NEW JERSEY DURING 1934

Severity of accidents	(*a*) Classified by Type of Roadway						(*b*)* Classified by Number of Lanes		
	State Highways		All Other Roadways in the State		Total		Two lanes	Three lanes	Four lanes
	Number	Percentage of total	Number	Percentage of total	Number	Percentage of total			
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)
Fatal	400	5.5	742	2.8	1 142	3.5	5.05	6.24	6.27
Non-fatal	3 768	52.3	15 069	56.9	18 837	55.9	50.23	54.51	52.59
Causing property damage	3 049	42.2	10 625	40.3	13 674	40.6	44.72	39.25	41.14

* Section (*b*) pertains to State Highways only.

It is interesting to compare this percentage of State highway accidents to total accidents with the percentage of State highway mileage to total miles of roads in New Jersey; for example, of the more than 35 000 miles of improved and unimproved roadways in the State, only slightly more than 1 500 miles, or nearly 6%, represent roadways under the jurisdiction of the State Highway Department. In other words, about 6% of the State roads are the scene of more than 21% of the accidents. Such a comparison, however, is not necessarily a measure of the hazards of State highways, as consideration must be given to the use made of them. Unfortunately, vehicle-mile data, segregated by the jurisdictions of the different classes of official bodies, are not available.

When comparing the severity of accidents on State highways with those on all other roads, it is found that, of the total State highway accidents, those involving fatalities, in percentages, equalled nearly twice the percentage of fatal accidents to total accidents for the remainder of the State, whereas a similar comparison for injury accidents showed a percentage slightly less than that for the remainder of the State. However, if pedestrian accidents are excluded from the results (as most accidents of this class occur in urban or built-up districts), it is found that the percentage of fatal and non-fatal accidents to total accidents is greater on State highways, in each instance, than on the remaining roadways of the State. This is the result of higher average speeds on State highways, of course, and a lesser enforcement of laws and supervision of activities in rural areas than in urban and built-up areas.

A comparison of pedestrian accidents occurring on State roads with those on the remainder of the State, indicates that, of the total pedestrian accidents on State highways, 25% concerned fatalities, whereas for all other roadways only 6% resulted in fatalities. This, too, is the result not only of greater speeds, but also of the lack of pedestrian sidewalks or pathways along most State highways, as well as lack of proper and sufficient illumination.

Accident Location and Time of Occurrence.—Of the total State highway accidents in 1934, 40.4% occurred at street intersections and the remaining 59.6% at intermediate points. It may be seen, therefore, that the sections of State highway having little or no cross-movements of traffic are the more hazardous. Accidents that occurred at night equalled 46.3% of the total, whereas those occurring during hours of daylight represented the remaining 53.7 per cent. Despite the fact that approximately one-fifth of the 24-hr traffic represents night-time travel, this lesser volume of traffic produces nearly one-half the accidents. In other words, it is more than three times as hazardous to drive at night as during the day.

Accidents per Million Vehicle-Miles.—To afford a comparison of accident experience and hazard on State highways of different widths, an analysis was made of accident rates on those roadways or parts of roadways having two, three, and four improved, hard-surfaced lanes used for the purpose of vehicular travel. Table 11 gives the results of this study.

TABLE 11.—ACCIDENTS PER MILLION VEHICLE-MILES, NEW JERSEY STATE HIGHWAYS, IN 1934

Number of lanes	Million vehicle-miles	Number of accidents	Number of accidents per million vehicle-miles
Two	1 178.78	3 241	2.75
Three	390.85	1 378	3.53
Four	483.21*	1 743	3.61
Total	2 052.84	6 362	3.10

* Includes about thirty miles of divided highway.

From this analysis it is determined that, for the State Highway System studied, the average accident rate equals 3.10 per million vehicle-miles, whereas on two-lane roadways the rate is 2.75, on three-lane roadways, 3.53, and on four-lane roadways, 3.61. In other words, an increased accident rate occurs with an increased width of highways; or (contrary to common belief) the wider the road the more hazardous it is. It is interesting, too, to note that, contrary to common belief, four-lane highways of the undivided type are more hazardous than three-lane roadways.

The writer does not mean by this statement that he supports or endorses the construction of three-lane roadways. However, the facts do prove (at least in so far as New Jersey is concerned) that the rate on four-lane roads is greater by 0.08 accident per million vehicle-miles than on three-lane roadways. There are many possible explanations for this condition, the primary one being that, the wider the road is, the more flexible will be the movement of traffic from one side to the other, unless congestion or enforcement prevents such movements.

A comparison of the severity of accidents on two-lane, three-lane, and four-lane roadways is shown in Table 10(*b*). It is seen that fatal accidents increased slightly with the width of the highway, whereas non-fatal and property-damage accidents fluctuated without regard to highway width. Segregating the accident experience of two-lane, three-lane, and four-lane roadways by accident types, it is found that the percentage of right-angle collisions decreased with the width, as did head-on collisions and fixed-object collisions. Same-direction accidents, however, increased with the width, and opposite-direction accidents (involving a left turn), and pedestrian accidents, fluctuated without regard to highway width. In other words, despite the increase in accident rates with increased width of highways, certain types of accidents conversely decreased, whereas other types increased, and still others fluctuated without regard to width.

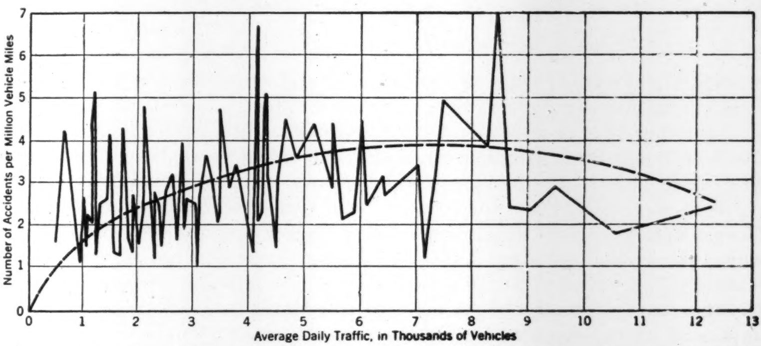

FIG. 4.—RELATIONSHIP BETWEEN DAILY TRAFFIC AND ACCIDENTS PER MILLION VEHICLE MILES FOR TWO-LANE ROADS

Relationship Between Daily Traffic and Accident Rates.—To determine the relationship between daily traffic and accident experience, a survey was made on two-lane roads, or on sections of two-lane roads, in the State Highway System, the results of which are shown in Fig. 4. It is interesting to note the rather definite relationship between daily traffic volume and the number of accidents per million vehicle-miles. In other words, as the average daily traffic increases, accident experience, on a million vehicle-mile basis, likewise increases to approximately 7 000 vehicles per day, which is considered by many authorities to be the capacity of a two-lane highway. Beyond that point, primarily because of congestion and the resultant decrease in speed and flexibility of movement during heavy traffic hours, there is a gradual decrease in the accident rate, despite the increase in traffic.

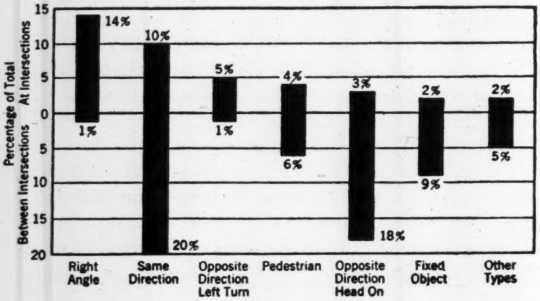

FIG. 5.—TYPES OF ACCIDENTS ON STATE HIGHWAYS

Types of Accidents.—An analysis of the extent of accidents of various types which have occurred on the New Jersey State Highway System will give an indication as to the probable degree of usefulness of some of the major highway improvements of to-day. Fig. 5 illustrates the relationship of various types of accidents to total accidents, arranged so as to compare those occurring at intersections and between intersections.

Assuming that it is physically and economically possible to reconstruct the New Jersey State Highway System to the extent of applying major highway improvements now familiar to the highway engineer, including controlled rights of way, in addition to physical separation or segregation of conflicting flows of traffic, adequate shoulders for stopping, pedestrian sidewalks or pathways, proper and sufficient highway lighting, plus other possible advanced features, 75% or more of the accidents that occur to-day could be avoided. In other words, the use of such highway safeguards would make it physically impossible to experience many of the types of accidents indicated in Fig. 5.

For example, a controlled right of way, prohibiting ingress to, and egress from, the highway, except at specific points where there are grade separations, would almost entirely correct the right-angle collision type of accident, as well as collisions between vehicles going in opposite directions with one making a left turn. A center island would prevent most head-on collisions and possibly, too, it might have some effect on same-direction, as well as other, accidents. Pedestrian sidewalks or pathways along major highways would have a materially favorable effect in reducing rural pedestrian accidents.

Furthermore, proper and adequate highway lighting, not only at roadway crossings, but also along sections of heavily traveled highways between crossings, will enable a reduction of all accidents, many of which are of the same-direction type, fixed-object type, as well as the pedestrian type, and which are chargeable to inadequate vision and illumination.

It is impossible, of course, to reconstruct the State Highway System in such a manner without prohibitive expenditures of money. However, much can now be done toward applying some of these so-called highway safeguards or major improvements. Such action will enable a reduction in accidents sufficient to make the necessary expenditures economically proper. Consider therefore, the accident experience as a result of the application of some of these improvements.

Accident Experience: "Before" and "After" Improvements.—Unfortunately, in most instances, major highway improvements on the State highways of New Jersey were constructed as a part of the initial system and, therefore, reliable "before" and "after" records are not available. In the case of divided roadways, however, it is possible to obtain some rather interesting and reliable "before" and "after" facts for parts of highways that have been converted from an undivided highway to that of a divided type. In the case of other major improvements, and where it has not been possible to obtain "before" and "after" records, interesting comparisons can be made indicating the usefulness of the improvement.

Divisional Islands.—Divisional or center islands that separate opposing flows of traffic, when properly constructed, make it practically impossible for motorists traveling in opposite directions to collide head-on. This type of highway construction has been used in New Jersey for the past several years but, until recently, proper and adequate "before" and "after" studies to determine the usefulness of such construction have not been possible. As a result of converting parts of State Highway Route No. 26 from a four-lane undivided highway to a four-lane divided highway (by sliding one lane of concrete to the side for a sufficient distance to permit the construction of a 12-ft center island, and adding an additional lane to make available a two-lane roadway on either side of the island), it has been possible to obtain "before" and "after" records for a rather limited period. Table 12(*a*) represents a "before" and "after" study on 2.1 miles of this highway in the Township of North Brunswick.

A review of Table 12(*a*) indicates a general reduction of 36% in accidents of all types, after the conversion. It will be noted, too, that not all types of accidents have decreased. Some indicate no change, whereas one type shows an increase. It is important to note, however, that this study—representing not only a rather short section of road but also a limited period of time (not quite five months)—is inadequate to determine with any degree of certainty that the conversion of this roadway to one of the divided type will eventually bring about such a reduction as is now indicated. Nevertheless, it is the writer's opinion that a reduction somewhat comparable to this will be shown as time goes on. Incidentally, all characteristics of the converted highway remained the same as before, with the exception of the construction of the center island as mentioned.

Another example of accident experience after the construction of a center island, but where the roadway was converted from a two-lane highway to a four-lane divided highway, is State Highway Route No. 25 in Cinnaminson and Delran Townships. Table 12(*b*) shows the results of a "before" and "after" analysis of this stretch of highway, representing approximately seven miles of road.

The study indicates a total reduction of more than 46% in all types of accidents, and whereas some types of accidents are reduced, others are increased, and still others remain the same. In this case, however, the reduction

cannot be entirely credited to the conversion of this highway into a divided roadway as, in addition to the construction of the 10-ft to 12-ft center island, the roadway width was increased from two lanes to four lanes plus a favorable straightening of the alignment in many instances. This study concerns a period considerably longer than that for Route No. 26 as can be noted from Table 12(*b*) and is, therefore, somewhat more indicative of the ultimate results of the improvement.

A further example of the effect of the construction of a center island, but where the improvement differed slightly from that of either of the two previous cases, and where the district is substantially urban rather than rural, is that of Route No. 25 in the City of Elizabeth. Table 12(*c*) shows a comparison of accident experience along 1.3 miles of this highway before and after the improvement. This thoroughfare was initially constructed with narrow islands on each side, approximately 4 ft wide and 20 ft from the curb lines, to segregate local traffic from through traffic. As the roadway width between curb lines was 96 ft, there remained approximately a 48-ft roadway in the center between islands for through traffic.

The improvement concerned the removal of the so-called local islands and the construction of a center island, 16 ft wide, down the center of the highway, leaving, therefore, a 40-ft roadway on either side of the center island. A review of Table 12(*c*) shows an increase of about 24% in total accidents after the improvement. Only two types of accidents have increased, however, and one of these types—same-direction accidents, primarily rear-end collisions—increased 100 per cent.

The increase in same-direction accidents is probably the result of improper re-location of signal units at the ten signalized intersections along this stretch of highway after the improvement, in a manner such that motorists traversing the highway can unmistakably receive a signal command sufficiently in advance of the crossing to govern their actions accordingly. It is planned to re-locate signal units properly along this highway, and to improve their operation; and the writer firmly believes that after this further improvement there will be a material decrease in this type of accident. Assuming that a decrease can be accomplished, it will be seen that the improvement of this stretch of highway—eliminating the so-called local islands and constructing a center island—will have a favorable effect on accident experience.

With regard to the improvements at all three of the aforementioned locations, it is interesting to compare the severity of accidents before and after the improvement. For example, on Route No. 26, in North Brunswick, fatal accidents decreased from 2 to none; injury accidents increased from 3 to 5; and property damage accidents decreased from 6 to 2.

On Route No. 25, in Cinnaminson and Delran Townships, fatal accidents decreased from 2 to none; injury accidents decreased from 14 to 5; and property damage accidents decreased from 14 to 11; and on Route No. 25, in Elizabeth, fatal accidents decreased from 2 to 1, injury accidents decreased from 48 to 19, and property damage accidents increased from 8 to 52.

Grade Separations and Traffic Circles.—Unfortunately, it has been impossible to obtain "before" and "after" records for intersections of highways separated by grade, and at traffic circles. However, it is interesting to make a comparison of accident experience at one of the first grade separations constructed in New Jersey with that of a signalized highway intersection along the same roadway only a short distance to the north; and also at a traffic

(*b*) INTERSECTION IN WOODBRIDGE TOWNSHIP, N.J.

(*d*) INTERSECTION IN NEW BRUNSWICK TOWNSHIP, N.J.

FIG. 6.—COLLISION DIAGRAMS (SEE CORRESPONDING DATA IN TABLES 10, 11, AND 12)

circle along this same roadway with that of a signalized intersection a short distance south of this circle.

Fig. 6(*a*), with Table 12(*d*), indicates the number and type of accidents that occurred on the Woodbridge Cloverleaf, where State Highway Routes Nos. 4 and 25 intersect; and Fig. 6(*b*), with Table 12(*e*), indicates accident experience at the signalized intersection of State Highway Route No. 25 and Avenel Street, a short distance to the north of the Cloverleaf. In this vicinity Route No. 25 averages approximately 25 000 vehicles daily, whereas State Highway Route No. 4 carries about 15 000 vehicles daily, or considerably more traffic than the local roadway intersecting with Route No. 25, shown in Fig. 6(*b*). In other words, despite considerably greater volume of traffic using the Cloverleaf grade separation there were nine less accidents than at the Avenel Street grade crossing for the same period. Of the six accidents at the Woodbridge Cloverleaf three were caused by motorists who, apparently in error, took the wrong roadway or proceeded beyond their turn, and then, in an effort to correct themselves (and in violation of traffic regulations), attempted to make a left turn where such a turn was prohibited.

Figs. 6(*c*) and 6(*d*), with Table 12(*f*), show a similar comparison but between a traffic circle and a signalized intersection. The collision data corresponding to Fig. 6(*c*) are:

Accidents due to approaching at right angles	1
Other accidents	1
Total	2

both cases being property damage only. In this case, the signalized crossing (Fig. 6(*d*)) is on the same highway only a short distance to the south of the traffic circle (Fig. 6(*c*)). The volume of traffic on Route No. 25 in this section equals approximately 13 000 to 15 000 vehicles per day. Despite the constant operation of traffic-control signals at the Georges Road intersection 26 accidents occurred there during 1934. Most of these accidents, however, were the result, either directly or indirectly, of the numerous left turns from the north to the east. Without doubt, a properly designed and constructed traffic circle at this intersection would greatly curtail these accidents.

Highway Lighting.—Unfortunately, reliable "before" and "after" studies enabling a determination of accident experience after the installation of highway lighting, are not available in New Jersey. As a result of a survey made along parts of Routes Nos. 25 and 26 in New Jersey (the first of which is properly lighted with up-to-date equipment, whereas the part along Route No. 26 has no lighting whatever, except at a few isolated points or intersections) some rather interesting facts were developed. These facts were reported in a paper entitled, "Relation of Highway Lighting to Highway Accidents," presented before the New York Section of the Illuminating Engineering Society, in 1934.[11] The conclusions arrived at as a result of this study were, in part, as follows:

"* * * there is a definite relationship between highway lighting and highway accidents and * * *, in general, where highway lighting is adequately provided, there is a substantial reduction in night accidents. This reduction in night accidents results in an economic saving in all cases in excess of the cost of providing street lighting, not mentioning, of course, the suffering and sorrow which inevitably accompany motor vehicle accidents."

---

[11] Not published.

Other Improvements.—There are many other highway improvements, of course, which may be classed as major improvements and which have a favorable effect on accident experience. Such improvements might include better sight distance at curves and hills, as well as at street intersections; flatter crowns and curves; shoulders wide enough to permit vehicles to park off the normal traveled part of the highway; and the proper use of standard signs, signals, and markings (and these only at locations where they will perform useful functions).

CONCLUSIONS

Safety on the streets and highways depends upon the application of proper "safeguards" as well as the use of proper "safe practices"; that is, unless and until the highways as well as motor vehicles are provided with proper and adequate "safeguards" and the highway user performs "safe practices" when making use of these facilities, the motor-vehicle accident problem will not be solved.

Properly designed and applied, major highway improvements or "highway safeguards" will generally produce a favorable effect upon traffic accidents. In other words, such improvements designed for safety make it less possible for highway users to perform improper practices that cause accidents. Even these improvements, however, are not cure-alls and, with streets and highways as they generally exist to-day, and the impracticability of their immediate re-construction, it is necessary through educational endeavors and enforcement activities to cause drivers and pedestrians alike to practice safe highway habits, as well as to maintain the proper attitude toward the other fellow when on the highways. Such campaigns will do much to curtail the horror and suffering now caused by motor-vehicle accidents. A most fruitful field of educational endeavor to-day is that of teaching the safe use of the highway to young and prospective drivers.

ECONOMICS OF ALIGNMENT, GRADE, AND WIDTH

BY E. L. SCHMIDT,[13] ESQ.

SYNOPSIS

The preceding papers of this Symposium have dealt with causes of traffic congestion and accidents, and have opened a discussion as to necessary remedies. No adequate discussion of this subject would be complete without summarizing the factors relating to cost, and that is the burden of this paper.

INTRODUCTION

The function of a major highway is to connect two or more centers of population and commerce by a roadway and its appurtenances. In the old days, before and during the early stages of the automobile, the guiding principle in considering the relative merits of two or more locations for proposed highway projects was the question of direct costs, and usually the best route was deemed to be that upon which the improvement could be constructed at the least outlay of funds. On the basis of the then existing light volumes of vehicular traffic this probably was not bad economics. As a result of this application of concept, however, most highways at that time followed the "lines of least resistance" to construction problems and rode upon the back of Mother Nature's surface, following contours, hills, and valleys. The consequence, in territory where topography was not kindly subdued, was roads of irregular alignment, heavy grades, and narrow widths.

With the rapid development of the automobile gradually came the realization that costs other than the direct payment of highway construction were involved. The riding public was asked to pay these bills, and rightly so; but if the design of the highway for which this public paid was such as to make him travel longer distances, require greater time, and combat more accident hazards than would be necessary over other possible alternate routes, then this public obviously would be paying proportionately higher costs for automobile operation and probably a greater total price for highway use than would be required with improved and more costly location and development. This condition prompted highway designers to inquire into the question of operation costs. Considering it from this angle alone, the ideal highway would be the one that followed a straight line, was of practically uniform grade throughout, and, of course, provided sufficient traffic-carrying capacity. Such a highway often would not justify the expenditures that would be required to overcome the obstacles of Nature and property developments. Thus, for the conditions of to-day in general, neither extreme is proper. The problem now usually resolves itself into the determination of the most economical highway—the one which will connect the points of termini in the shortest possible traveling distance consistent with reasonable convenience and safety of travel and the economics involved.

---

[13] Pittsburgh, Pa.

HIGHWAY ECONOMICS

The costs involved in highway construction have been designated "direct" and "indirect." Direct costs include all expenses for the actual physical construction of the highway improvement. They consist of the following: (1) Right of way and damages; (2) construction; (3) overhead; and (4) depreciation and maintenance. The indirect costs are: (5) Automobile operation; and (6) automobile accidents.

These costs are not all the factors of value that should be considered in highway improvement problems. Among others, two very important factors to be considered are the values of scenic and beautification advantages, and the values that may accrue from the appreciation of property. The former is an intangible consideration and difficult to evaluate; the latter is more easily measured; but this paper is confined to considerations of highway economics from the point of view of traffic.

Traffic Considerations.—When considering two or more locations and types of development for a proposed highway, the most economical route will be that which requires the least annual expenditure for fixed charges, automobile operation costs, depreciation, and maintenance.

In order to make this determination, it becomes apparent that the starting point in the analysis of all highway problems is traffic. The first question to be answered is "What are the volume and characteristics of traffic likely to be during the life period of the highway improvement?" In the past, this has been difficult to foretell because of the almost unbelievable advance of the automobile. However, it seems that future forecasts will be somewhat easier because primarily the volume of traffic bears a proportional relation to population gain, which is decreasing and probably will continue to decrease to a point of practical stability. Moreover, the ownership of automobiles, now at slightly less than one per five persons, surely must be approaching a "point of saturation." Although the average daily use of cars probably will continue to increase, a practical limit cannot be far remote. Certainly, automobile manufacturers cannot continue forever to install more and more speed in their new models. Their appeal to the wants of car owners, of necessity, will have to be in other directions, such as greater safety and comfort, and in simplifying operation technique so that practically every one can drive with ease. The necessary analysis of traffic demands should be made with these and other considerations in mind.

No general statements can be formulated as to what the average conditions may be because the volume and characteristics of highway traffic are changing continuously from section to section. The only way to make a reasonably accurate determination is by means of a careful and painstaking study of the local circumstances of the problem. In general, however, traffic characteristics may be classified somewhat in accordance with the type of community development through which the highway is traversing. For example, in the commercial districts, practically always, the traffic volume is relatively heavy and speed is restricted. In the urban residential sections, traffic volume is less; but usually it is still high, and the average speeds generally are advanced. In rural residential and further outlying rural sections, traffic volumes have diminished to a relatively small value but, on the other hand, speeds have been materially increased.

Standards of Width, Alignment, and Grades.—It is obviously impossible to establish "hard and fast" general standards in regard to desirable highway designs for these different types of development districts. Every single highway problem must be studied and treated in the light of its own peculiarities, and it can be stated without danger of dispute that no two sets of conditions will ever be found to be exactly the same. Nevertheless, there is usually a general similarity between problems that may arise in similar community sections and an attempt will be made herein to define standards that will fit the rule.

Commercial Districts

It is easy to define desirable minimum standards of width, alignment, and grade of major highways that traverse commercial districts, but it is quite another problem to secure the general adoption of such standards. The simplest rule would be to have no major thoroughfares routed directly through commercial sections of any magnitude or importance. Quite often, of course, this rule is not practicable, although there is a decided definite trend toward the by-passing of major thoroughfares around congested business sections. In Pittsburgh, Pa., there is an excellent example of the unnecessary burden of traffic which is superimposed upon city streets because the major thoroughfares leading from outlying districts converge and become a part of the downtown street system. Almost 50% of the local traffic in the business section of Pittsburgh is there, not because of a definite destination in the section, but because it is forced into the "Triangle" due to the absence of adequate by-pass routes. In order to correct this situation, it is proposed to construct a boulevard type of highway along the Monongahela and Allegheny River fronts which, in turn, will connect with a proposed cross-town thoroughfare in the vicinity of the Pennsylvania Railroad Station in Pittsburgh. The cost of this river-front improvement probably will be approximately $5 000 000. No doubt it will be justified time after time, however, by the value of accommodation which it will afford traffic.

In a commercial district, where there may be no choice but to utilize the existing street system for major highway use, attention should be directed toward selecting those streets that are best adapted for the purpose. Wherever possible, streets should be chosen that will afford convenient movement for through traffic with the least interference to local traffic. Of course, no rule can be made for this determination. It can only be solved by a study of the conditions at hand. However, in a commercial district, the hourly traffic almost always will exceed the working capacity of a two-lane roadway for moving vehicles and, therefore, wherever possible, such streets should be selected as will provide capacity for four moving lanes—two in each direction—as well as adequate provision for parking spaces. Generally, six lanes for moving vehicles on one street within the limits of a single roadway, is not advisable, even if there may be evidence of congestion on the four-lane highway. Where it appears that there is need for additional traffic capacity, it is probably better to devise methods by which part of the traffic may be diverted into other streets.

In commercial sections, because of interference caused by traffic on intersecting streets, parked vehicles, pedestrian movement, street cars, and the other usual factors, automobile velocity generally is quite low, probably varying from 10 to 25 miles per hr and averaging about 15 miles per hr. At this range of speeds, the question of alignment does not present any troublesome problems. As long as there are no awkward effects, movement of traffic would not be retarded nor accident hazards increased because of short radius curves. At street intersections, it is desirable, if possible, to provide minimum radii of approximately 50 ft in order that large buses and trucks may turn without causing interference in other lanes of traffic.

The maximum grade in commercial districts, where justified economically, should not exceed 4 per cent. In old established and concentrated business sections, highway improvements, such as providing better alignment, reduced grades, or increased widths of roadways, usually will require enormous direct costs due to the high values of property along the right of way. Ordinarily, in order to justify these expenditures, the advantages that will accrue from the improvements must be of considerable magnitude.

Urban Residential and Other Outlying Districts

Outside the commercial districts, traffic characteristics will vary considerably, and desirable minimum standards of alignment, grade, and width of highways will depend upon the conditions peculiar to the problem in question. In general, it may be stated that the desirable curvature, gradient, and width of roadway, depend upon the volume and speed of the traffic that probably will use the highway, as well as the general topography of the territory in which the improvement is to be made.

Physical Characteristics

Widths of Roadways.—The determination of roadway widths is fundamentally a study of roadway lane capacity. Ordinarily, the definition of lane capacity has been interpreted as the maximum number of vehicles that can pass a given point on the highway, in a given time, at specified speeds. This measure of capacity, an arithmetical computation, has been determined frequently and it has been found possible, without interferences, to pass 2 000 cars per lane per hr, at a speed of 20 miles per hr. This finding, however, has no real practical value since there is no consideration given to the speeds that drivers would naturally be inclined to follow in the absence of limitations imposed by traffic, and no clue as to the point where congestion may be said to begin. The latter is an extremely important consideration since it determines, more or less, the time when attention should be given to the question of highway capacity improvement.

A better definition of capacity was given by the Highway Research Board, National Research Council, at its Eighth Annual Meeting in 1931, as follows:

"The traffic capacity of a roadway is reached when any further increase in traffic volume, all other factors remaining constant, results in a marked decrease in traffic speed." This interpretation of traffic capacity is significant because it indicates the point at which any additional traffic will begin to result in retardation of traffic movement. Bruce D. Greenshields, Assoc. M. Am. Soc. C. E., appropriately designates such capacity as the "working capacity" of the highway. As the result of experiments conducted by him in 1934, on Ohio State highways, by which traffic volumes and speeds are recorded and correlated, he reaches the conclusion that the average automobile driver (if not most drivers) will operate his car at a speed of about 44 miles per hr, whenever traffic conditions permit him to drive as he sees fit. Professor Greenshields designates this velocity as "free speed" and finds that it obtains a density of approximately 400 cars per hr on a two-lane highway, with a varying percentage of truck traffic to 10%, and with traffic about equally divided in both directions. Whenever traffic exceeds this density, velocity begins to decrease. Apparently, however, the decrease in velocity could not be called marked until a density of approximately 600 to 700 cars per hr is reached.

These experiments "dovetail" with the arithmetical computations made by Sigvald Johannesson, M. Am. Soc. C. E., who computes "working capacity" of a two-lane roadway as approximately 200 vehicles per hr per lane. At this density, vehicles are likely to be spaced so as to permit passing in both directions with reasonable safety.

The writer substantiates these findings by his local experience and observations. It is his conclusion that the working capacity of a two-lane roadway approximates 600 vehicles per hr, and he would recommend that whenever it is found or estimated that the average daily density of traffic exceeds this value for 3 hr or more of the day, consideration should be given to the economics of widening.

In the Pittsburgh area, a maximum hourly density of 600 cars on a two-lane highway (as determined by a comprehensive traffic survey conducted in 1934 under the direction of John M. Rice, M. Am. Soc. C. E.) is equivalent to a total volume of approximately 5 000 cars per day. It is interesting to note the comparison between this volume and the standard of practice for road design established by the American Association of State Highway Officials. This group recommends a roadway capacity of more than two traffic lanes in cases where the average daily volume exceeds 4 000 vehicles.

Two lanes for moving vehicles, of course, is the minimum for any highway. Whenever traffic conditions indicate the need of widening a road, or the construction of a new highway of greater capacity than two moving lanes the change should be from a two-lane to a four-lane roadway. Only in exceptional cases should the widening from two to three lanes be considered. Although the addition of one lane will increase capacity very materially, it usually will convert the highway into a most dangerous thoroughfare.

A highway with four lanes for moving traffic will carry a large volume, probably (under favorable conditions) as great as 50 000 cars per day without appreciable congestion. Where more than four traffic lanes seem to be needed to take care of the traffic, most likely it will be found better to construct an additional thoroughfare.

Because of the seriousness of head-on collisions, the present tendency is to advocate the construction of a divided roadway with two or three traffic lanes for each direction instead of a four-lane pavement. This type of development, certainly, is desirable and, wherever economically justified, should be provided. The width of separation between roadways, where provided, will depend upon the character of local conditions and may vary from a few feet to as many as several hundred feet or more. Wherever possible the minimum distance between directional roadways, at least where cross-overs are provided, should be 40 ft. This will permit vehicles to turn from the inside lane of one roadway to the inside lane of the other without obstructing the traffic movement in other lanes of travel. Where there is considerable truck or slow-moving traffic, consideration should be given to the desirability of providing, physically or by regulation, separate lanes of travel for this traffic.

Curvature.—The most important reasons for curvature and variations in alignment are: (*a*) To make the highway serve intermediate points between the principal termini; (*b*) to decrease damage, right-of-way, and construction costs by the utilization of existing locations, or by taking advantage of favorable topography or other natural conditions; and (*c*) to reduce the rate of grades by lengthening the distance of travel. Except as it affects distances, curvature does not appreciably affect the cost of motor-vehicle operation, provided proper radii and length, super-elevation, sight distances, and roadway widening are made part of such curvature. The desirable magnitudes of these factors depend mostly upon the rate of speeds at which traffic will move normally. On a two-lane roadway, the standards should be more liberal than those for a four-lane highway where directional traffic is confined to its own lanes.

The desirable minimum standards of curvature and sight distances are as follows:

Item:	Desirable minimum standard:
Sight distance, in feet	800
Horizontal curvature; radius, in feet	1 000
Vertical curvature; sight distance, in feet	500

In each case these are desirable minimums and should be exceeded wherever practically possible. However, in territory such as Western Pennsylvania, because of the rugged terrain and topography, it sometimes becomes expensive, and not economically justified.

Current practice in Allegheny County is to superelevate all curves on a two-lane roadway which are in excess of 1° curvature. As a rule, the superelevation is fixed at $\frac{1}{8}$ in. per ft of width per degree of curvature, with a maximum superelevation of 1 in. per ft. On four-lane highways, superelevation usually is provided, but the extent and design ordinarily are determined by special study of each individual case rather than by the results of fixed formulas.

Grades.—The rugged topography in the Pittsburgh territory does not lend itself to the construction of grades as low as those in many other sections of the United States. Engineers in the region, of course, attempt to keep grades as low as practicable and try never to exceed a maximum of 8 per cent.

COSTS AND SAVINGS

Direct Costs.—The sums that are expended for the direct cost items in the improvement of highways vary materially, and it is difficult to determine the exact effect which alignment, grade, and width have on these items. Costs of rights of way and damages are the most variable, and in the writer's experience have ranged from $15 000 to $100 000 per mile. In commercial districts, obviously, this item is usually high and may constitute the major part of total direct costs; or, in fact, in many instances, it may cause the cost of a proposed improvement to be prohibitive, making it necessary to construct a highway along an alternate route. In sections outside commercial districts, this item of cost decreases with the intensity of development and the extent of property values.

In Allegheny County, a fair average cost for 60-ft rights of way and damages in districts outside of commercial and highly developed residential areas, is about $25 000 per mile. For a 100-ft right of way, the corresponding cost probably would average about $40 000 per mile, provided no material building developments were encountered. These averages give a reasonable measure of the probable difference in cost of rights of way for a highway in Allegheny County with two lanes and four lanes for moving vehicles.

Cost of construction does not cover the wide range of variation per mile of highway as rights of way and damages; and, unless influenced by peculiar or unusual construction problems, such cost is practically the same in the different types of community districts. For the type of development customary in connection with two moving vehicular traffic lanes, construction costs in Allegheny County average about $75 000 per mile. Where four lanes for moving vehicles are provided, construction costs average about $140 000 per mile. Thus, on the average, the cost of constructing a four-lane highway is about 1.86 times that for a highway with two lanes for moving traffic. This is a measure of the effect of width on the direct costs of major thoroughfares. This additional expense, of course, is offset by reduced automobile operation costs.

As already stated, the effect of introducing curvature and grades into a highway usually is to reduce construction costs. However, where it becomes desirable, or necessary, or economically justifiable, to reduce grades or improve alignment on existing highways, the effect is to provide a highway of greater direct cost than the existing one that is being replaced.

Cost of overhead (being composed of expenses for contingencies, engineering, organization, interest, office, legal, and similar items which bear a relation to both rights-of-way and construction costs) is affected, therefore, by the range of variation in these two cost items. Overhead costs usually are expressed as percentages of the total estimated cost of the improvement. For conditions in Allegheny County, overhead costs average about 15% of the total estimated costs of rights of way and construction, and on the basis of the average values given for these items, would equal about $15 000 to $27 000 per mile for highways with two and four traffic lanes, respectively.

Cost of maintenance is a continuously recurring charge in contrast to the other direct cost items, which are non-recurring. Maintenance varies principally with the construction cost item and reflects expenditures for keeping the highway in proper condition for traffic use. Obviously, it varies mostly with width of pavement, but alignment and grades also affect this cost item since there is more "wear and tear" and need for conditioning pavements as the sharpness of curvature and grades increases. Experience with high-type road construction in Allegheny County indicates that the annual cost of maintenance, covering all items for a two-lane roadway, averages about $1 000 per mile, and about $1 200 per mile for four-lane highways.

Indirect Costs.—Various attempts have been made to evaluate the benefits to traffic that accrue by the reduction of travel distances, traffic delays, and traffic danger hazards. Except for the question of traffic hazards, the bases of such estimates are automobile operation costs, and include the items of gasoline, lubrication, tires and tubes, maintenance, depreciation, license, garage, interest on investment in car, insurance, taxes, and sometimes driver's wages. In a study made by Thomas R. Agg and Harold S. Carter, Members, Am. Soc. C. E., in 1928,[14] it was found that the cost of operation of the average passenger automobile which traveled 11 000 miles per yr, was 5.44 cts per mile when operating on high-type road pavements. Mr. Johannessen concludes[15] that the average operation cost of passenger cars used for private purposes at that time amounted to 7.5 cts per mile, based on an annual 10 000-mile use; that the cost for passenger cars used for business purposes on the same annual mileage basis was 12 cts per mile; and that about two-thirds of the passenger cars are used for pleasure and one-third for business. In a similar manner, other estimates have been made for the cost of truck operation and the results have been found to vary from approximately 20 to 70 cts per mile, depending upon the size and tonnage capacity.

In Allegheny County, as the result of various traffic surveys, the average conditions seem to be as follows:

Passenger traffic (percentage)	80
Pleasure purposes (percentage)	70
Business purposes (percentage)	30
Truck traffic (percentage)	20
Average truck capacity, in tons	1.5
Average annual mileage	12 000

Based upon these averages the writer's estimates of automobile operation costs are as shown in Table 13. These unit costs are the bases for the following evaluation of benefits arising from highway improvements which affect reductions in travel distance, traffic delays, and danger hazards.

Saving by Reduction in Distance.—Distance affects both operating costs and time, but consideration is given herein only to the economics of the former, as the value of time will be considered separately under the heading, "Reduction of Traffic Delays." The values in Columns (2) to (5), Table 13, will be affected directly by any reduction of distance, assuming that ample roadway capacity is provided for traffic, but the total annual sums spent for the other values will not be changed to any significant extent.

---

[14] *Bulletin 91*, Eng. Experiment Station, Iowa State Coll., Ames, Iowa.

[15] "Highway Economics," by Sigvald Johannessen, M. Am. Soc. C. E., 1931.

These operation costs become 3.75 cts for passenger automobiles (pleasure or business purposes), and 9.83 cts for trucks. Based on a distribution of 80% passenger cars and 20% trucks, the average cost per vehicle amounts to approximately 5 cts per mile or about 1 ct per 1 000 ft. At this rate the annual savings due to a reduced traveling distance of 1 mile for 5 000 cars per average day amounts to $91 250. This is equivalent to a capitalized cost (at 6% interest) of $1 520 000, and is a measure of the sum of money that can be expended justifiably to reduce the traveling distance for an average daily traffic of 5 000 vehicles by 1 mile. Expressed in other terms, these results indicate that under the conditions assumed, the annual expenditure of about $57 500 will be justified to reduce the travel distance 1 000 ft per 1 000 vehicles per day. Among other methods, such reduction of distances can be accomplished by improving the alignment and reducing the grades.

TABLE 13.—ESTIMATE OF AUTOMOBILE OPERATION COSTS, IN CENTS PER MILE (12 000 MILES ANNUALLY)

Vehicle	Gasoline	Lubrication	Tires and tubes	Maintenance	Depreciation	License	Garage	Interest	Driver's wages	INSURANCE		Total
										Fire and theft	All accidents	
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)	(12)	(13)
Passenger:												
Pleasure	1.33	0.36	0.40	0.83	1.66	0.13	0.42	0.50	....	0.10	0.83	6.56
Business	1.33	0.36	0.40	0.83	1.66	0.13	0.42	0.50	5.00	0.10	0.83	11.56
Trucks	3.00	0.63	1.10	3.00	4.20	0.40	0.50	1.50	7.50	0.25	1.25	23.33

Savings by Reduction of Delays.—The value of savings in traffic delays has been estimated as from 1 ct to 2 cts per vehicle-minute. Under the conditions that prevail in Allegheny County a fair and conservative value is 1.25 cts. This may be supported upon an analytical basis either by placing a reasonable value upon the rider's time or by expressing the fixed charges on a minute-of-time basis. However, an actual practical basis has greater meaning and, therefore, the writer refers to such an example in the Pittsburgh District. For a part of the suburban South Hills Section two routes are available for travel to downtown Pittsburgh, one of which, between common points, is 5.7 miles long and the other is only 4.0 miles. However, there is considerable traffic congestion on the shorter route and the average travel time for the 4 miles is about 13.5 min, whereas the longer route can be traversed in 9.5 min. Because of the greater convenience of travel and the shorter time required for those to whom both routes are available, drivers of passenger cars invariably select the longer one. This means that in so doing, preference is given to spending about 6.5 cts more for operation costs in order to save 4.0 min. On this basis the value of a vehicle-minute would be 1.6 cts. Considering all the circumstances involved in this example, and the theoretical computations used, 1.25 cts is a conservative value. Its significance is that wherever a highway improvement—either by providing greater width, better alignment, reduced grades, by-passing of congested areas, or by any other means—results in a reduction of travel time, the value of this reduced time is equivalent to 1.25 cts per vehicle-minute under the average conditions that prevail in Allegheny County. Using the example of 5 000 vehicles per average day, the annual savings of 1 min per vehicle would equal $22 800, or an equivalent 6% capitalized cost of $380 000. On the basis of 1 000 vehicles per day this would be $76 000.

Savings in Reduction of Accident Hazard.—The economic loss caused by traffic accidents in the United States has been estimated at about $3 000 000 000 per yr. On the basis of 10 000 miles per vehicle, this is equivalent to an average accident-hazard value of about 1 ct per vehicle-mile. This is a general measure of a value that may be applied where reduction of accident hazards is accomplished by highway improvement. Of course, a better method is to study the accident proneness and the costs of the particular highway or section of highway under consideration and, thereby, derive a value that will be more applicable to the conditions at hand.

In a general presentation of this kind, it is practically impossible to evaluate savings due to reduction of traffic accidents and, therefore, no consideration is given to such values in the following specific examples.

EXAMPLES

The effects of alignment, grade, and width on the direct and indirect costs of major highways cannot be equated, varying as they do for each individual highway improvement. In general, however, curvature is introduced into a highway to reduce rights-of-way, damage, or construction costs. The introduction of such curvature does not materially affect vehicular operation costs in so far as the reduction of traffic speeds are concerned, provided such curvature is of proper radii, length, and superelevation, and if it provides good sight distance. If it increases traveling distances, curvature obviously increases vehicular operation expenses.

The economics of grades is difficult to evaluate. Where grades are introduced in order to fit topography, the effect is to reduce construction cost. Provided such grades do not exceed a rate of about 6%, and if there is sufficient width of roadway and sight distances, the cost of vehicular operation does not become a particularly significant factor. On the other hand, where heavy cuts and fills are made in order to reduce grades to desirable standards, or to decrease the distance of travel or the need for curvature, the effect is to increase construction costs materially but, compensatingly, to decrease vehicular operation costs. The provision of additional width causes a slight increase of rights-of-way and damage costs and a heavy increase in construction costs. On the other hand, however, such improvement increases vehicular speeds and, consequently, lessens vehicular operation costs.

Case 1.—The application of the economics of highway improvement can best be illustrated by reference to specific examples. In 1936, a study was made of a proposed major highway extension in the Pittsburgh area. The proposed improvement was about 3 miles long and it was estimated that the average annual traffic during the next 20 yr would approximate 2 000 000 cars per yr. The problem resolved itself into two alternatives, one of which would adapt the location of the highway to topography, involving curvature and grades, and would make the line about 3.6 miles long. The other location was more direct (about 3.0 miles long) but would involve considerable cut and fill and the construction would cost about twice as much as the longer route. The economics of this problem were as shown in Table 14. Project B, the shorter but more costly project in so far as direct costs apply, is the more economical.

TABLE 14.—ECONOMICAL COMPARISON, ROUTES A AND B

Project (1)	Length, in miles (2)	Total physical cost, in thousands of dollars (3)	ANNUAL COSTS, IN THOUSANDS OF DOLLARS					
			Interest at 4% (4)	Depreciation (5)	Maintenance (6)	Vehicular operation		Total (9)
						For distance, at 5 cts per mile (7)	For time, at 40 miles per hour (8)	
A	3.6	500.0	20.0	12.5	3.6	360.0	135.0	531.0
B	3.0	1 000.0	40.0	25.0	3.0	300.0	112.5	480.5

Another excellent example is the Liberty Tubes. These are twin vehicular roadways, about $1\frac{1}{8}$ miles long, constructed by tunneling through a steep hill known as Mount Washington, so as to connect down-town Pittsburgh with the South Hills (residential) District. Although they are exceptional in character, the tubes are nothing more than a four-lane highway. However, the construction cost of this highway was more than $5 000 000 per mile. Nevertheless, in overcoming obstacles of topography to eliminate excessive curvature, grades, and distances, this expenditure has been justified over and over again by the value of the accommodation to traffic. It has resulted in a daily savings of both time and distance to about 25 000 cars, which is equivalent to more than 9 000 000 vehicles per yr. Without recourse to any computations, it is apparent that this convenience is easily worth 10 cts per vehicle. At this rate, the annual savings to traffic is $900 000. Capitalized at 6%, the worth of this savings is $15 000 000. On the other hand, if this improvement had only affected, in the same manner, 1 000 vehicles per day, the annual savings would be only $36 000 which, capitalized, would represent approximately $600 000. Under the latter condition, it would be obviously impossible to justify the $5 500 000 construction cost. Incidentally, this particular improvement is an outstanding example of one which has resulted in a tremendous appreciation of property values. In one township alone, in the South Hills area, affected by the construction of this project, the assessed value of property has increased from $8 000 000 to $29 000 000 within 10 yr after its opening in 1924.

Case 2.—One other splendid example of the economics involved by improvement of alignment, grade, and width, is the so-called Westinghouse Cut-Off. This is a relocation improvement of the Lincoln Highway in an area immediately outside the city limits of Pittsburgh. Between common points, the old route, 3.5 miles long, provided capacity for two moving lanes. Of the total 3.5 miles approximately one-third followed an indirect route through a heavily congested commercial district and the remaining two-thirds was routed over a hillside, resulting in an average rate of grade of about 10%, and several extremely sharp curves. The average time for traffic to travel this old course was 14 min.

The new highway, following an entirely new location, is 2.5 miles long, has a capacity for four lanes of moving vehicles and provides a practically uniform grade of 4 per cent. To accomplish these improvements it was necessary to make very heavy cuts and fills, the maximum of each exceeding 120 ft. The total physical costs amounted to almost $3 000 000, of which 42.5% was for rights of way and damages. The average travel time over the new route is 4.3 min.

The annual charges for interest at 6%, depreciation, and maintenance, amount to $333 000. Offsetting these charges, the annual costs of automobile operation have been reduced at least $425 000 due to the value of the savings in time and distance to the 2 500 000 vehicles at present utilizing the highway.

Conclusion

It is impossible to present general formulas of the effect of alignment, grade, and width on the direct and indirect costs of major highways. This applies particularly to direct costs because of the extreme variations of physical conditions throughout the United States. This paper has outlined the procedure followed and the experience gained in Allegheny County. Because of the ruggedness of the terrain, the problems are much more difficult, and the direct costs heavier, than in most other sections. This results in greater expenditures for value received. In practically all cases, however, the engineers concerned have been able to justify the expenses for major highway improvements.

DISCUSSION

JOHN A. OAKEY,[16] ASSOC. M. AM. SOC. C. E. (by letter).—Work such as that described in this Symposium does much toward establishing traffic engineering as a practicable science. However, there is one item in the section dealing with the "Economics of Alignment, Grade, and Width," as presented by Mr. Schmidt which, in the writer's estimation, requires further consideration. That item is the cost of operating a motor vehicle.

Ever since Agg and Carter[14] published the results of their investigation on the cost of operating a passenger car, these results have been accepted with little or no consideration of the fact that motoring costs have undergone radical changes since 1928. These findings, based upon an annual travel of 11 000 miles, are presented in Table 15, Columns (2), (3), and (4).

The results of studies[15] by Mr. Johannesson on the cost of operating a passenger car, are shown in Table 15, Column (5). These values are based upon an annual travel of 10 000 miles and show a total somewhat in excess of those of Agg and Carter. In other words, according to these authorities, the annual vehicle cost for the average motorist lies between $700 and $750. A momentary consideration of the fact that the average motorist has an annual income surely not exceeding $2 400 seems ample proof of the fact that motoring costs cannot be this high. If they were, there would not be 25 000 000 passenger cars in operation in the United States.

The writer has no experimental data to support his contention that these costs are excessive other than his own experience and that of his acquaintances, and certain statistics published by the Automobile Manufacturers' Association.[16a] It is interesting, nevertheless, to study each item in Table 15, Column (1), from a common-sense viewpoint and with full consideration of the habits of the average motorist of to-day.

(*1*) *Depreciation.*—In 1936, the average passenger car had an f.o.b. price of $603. The average retail price, therefore, was approximately $750. This car travels about 9 000 miles per yr and has a life slightly greater than 8 yr. It is fair, therefore, to assume that the life is 75 000 miles. On this basis, the depreciation is 1.0 cts per mile (see Table 15, Column (6)).

(*2*) *Gasoline.*—The average cost per gallon of gasoline was 18.84 cts in 1936. Assuming that the average car makes 15 miles to the gallon, the fuel cost is 1.2 cts per mile. The values in Table 15, Columns (3) and (5), based upon the same mileage per gallon but upon a fuel cost of 20 cts per gal, are, therefore, quite reasonable. The annual gasoline consumption of the average passenger car is 600 gal, giving a total annual travel of about 9 000 miles.

---

[16] Asst. Prof., Civ. Eng., Villanova Coll., Villanova, Pa.

[16a] "Automobile Facts and Figures," Automobile Manufacturers' Assoc., 1936 Edition.

(*3*) *Lubrication.*—The average motorist changes the oil in his car between the 1 000-mile and the 2 000-mile mark. Assume that he changes the oil at the 1 500-mile mark, that the change requires 6 qt of oil costing 25 cts per qt, and that he finds that he requires an additional quart between changes. Assume further that he has his car greased every 3 000 miles at a cost of 50 cts. These assumptions place the total cost of lubrication at $2.00 per 1 500 miles, or 0.13 ct per mile. However, since no consideration has been made of the fact that many thousands of motorists service their own cars with chain-store products at a considerable saving, this item may reasonably be reduced to 0.1 ct per mile.

TABLE 15.—COMPARISON OF OPERATING COSTS, IN CENTS PER MILE

Description	AGG AND CARTER			Johannesson	Writer
	High type of roads	Intermediate type of roads	Low type of roads		
(1)	(2)	(3)	(4)	(5)	(6)
Fuel	1.09	1.31	1.61	1.39	1.2

(*4*) *Tires and Tubes.*—The modern light-weight average car can be equipped with tires and tubes at a cost not exceeding $50. These tires will have a life between 15 000 and 20 000 miles. On this basis, the tire cost will be slightly less than 0.3 ct per mile. However, the slight additional cost of repairs will bring this item up to 0.3 ct per mile.

(*5*) *Maintenance.*—The writer has driven his present car almost 100 000 miles at a total maintenance cost of slightly less than $200. The resulting maintenance cost of 0.2 ct per mile, while simply the result from one car, appears as reasonable as the other values shown in Table 15. The latter represent annual total maintenance costs of $189 and $203, respectively, and are obviously much too high. Acquaintances of the writer have reported maintenance costs from $5 to $50 per 10 000 miles. In any case, an arbitrarily assumed annual maintenance charge of $45, or 0.5 ct per mile should be sufficient to properly maintain the modern average car.

(*6*) *Interest.*—For some unknown reason, whenever an engineer is confronted with a problem involving economics, he writes down as his first item of annual cost "6% on the investment." To the average motorist, his car is no more of an investment than are the clothes he wears. The argument is frequently raised that, if he had not purchased his car, the motorist could have put his money out at interest. The apparent logic of this argument is "exploded" when one considers that the motorist would get, at most, 3% from a savings bank and that 60% of all new cars and 65% of all used cars are purchased on the instalment basis. Apparently, a large percentage of the motoring public in this country lacks either the ability or the inclination to save. The dialogue composed of: "Now that you own a car, you'll be broke all the time," and "I'm broke all the time anyway so I might as well have the car," is indicative of the national habit of owning a car at all costs. For these reasons, a nominal charge of 1% on the investment, or 0.1 ct per mile, seems all that can be justified on this item.

(*7*) *Taxes.*—Passenger car and truck owners to the number of 26 200 000 paid $396 000 000 for registration fees and personal property, city, and county taxes in 1935. The average cost, with no attempt to segregate the two types of vehicles, is $15. This figure results in a cost of somewhat less than 0.2 ct per mile.

(*8*) *Garages.*—Storage charges vary from $15 per month in thickly populated urban areas to nothing in rural areas. The commonly accepted charge of $4.00 per month, resulting in a cost of 0.5 ct per mile, is reasonable.

(*9*) *Insurance.*—In 1935, the owners of the 26 200 000 passenger cars and trucks in the United States paid a total of $446 000 000 for all forms of automobile insurance, $242 000 000 of which were returned in losses paid. The net charge of $204 000 000 results in a cost of $8.00 per vehicle, or 0.1 ct per mile.

(*10*) *Miscellaneous.*—The writer is loath to venture an opinion as to whether such items as "time" and "driver's wages" can be given a definite value. The arguments from authorities on either side seem to be equally balanced. Abstract time, to the average motorist, has little value, except as a convenience. When weighing the respective values of time and mileage, he usually considers the cost of gasoline as his only mileage charge. Whether engineers have the right to make him pay for a saving he does not appreciate is a question which may be argued at great length.

From a consideration of the tangible items comprising the cost per mile, it would appear that this cost is about 4.0 cts per mile for the average passenger car. Items (6), (7), (8), and (9) and, to a certain extent, Item (1), are relatively unimportant since these items vary with time and are not affected by any saving in distance or betterment in type of surface. If one-third of the depreciation may be charged to time and two-thirds to usage, the saving resulting from a reduction of distance is 2.8 cts per mile. This is considerably lower than the commonly accepted values.

There is another aspect to the reduction of distance which is seldom considered. This is the effect of the relative length of the reduction. In railroad work, a sliding percentage is applied depending upon the length of the reduction. Unfortunately, it is impossible to break down motor-vehicle costs in a manner comparable to that successfully used by the railroad companies. Yet the effect of relative length of the reduction of highway mileage may be of sufficient importance to warrant some additional study. It requires no great imagination to see that the saving of 1 000 ft on a 25-mile trip would have less effect on motoring costs than the vagaries of wind and weather. As every one knows, a stiff head wind increases gasoline consumption considerably; but as yet, no one has suggested that highways be enclosed to prevent these head winds even although it may be proved, on the soundest of economic bases, that such a step would be justified in many cases.

In the foregoing, the writer has attempted to "iron out" one of the difficulties confronting the present-day highway economist. These difficulties are legion, but they cannot be solved by over-estimating the costs of vehicle operation. Other important and still uncertain basic elements in economic analysis also come to mind. What is the probable life of this particular piece of pavement? What will the maintenance charges be? What will the average traffic volume be? With what savings to the motorists may one credit the pavement during its life? These are some of the questions that must be settled. In time, engineers may be able to accumulate sufficient data to permit their successful solution. It is doubtful, however, if highway economics will ever become sufficiently exact to permit its application in anything but the broader aspects of highway planning. Within certain broad limits, highway economics will be useful in justifying certain projects. These justifications, however, will continue to be swayed by the dictates of politics, safety, preservation of natural beauty, and improvement of recreational or educational facilities.

L. W. Mahone,[17] Assoc. M. Am. Soc. C. E. (by letter).—Quoting Mr. McNeil (see heading, "Remedies for Delays Due to Marginal Interference"): "It is an admitted fact, substantiated by the Courts, that streets are primarily for the purpose of the moving vehicle." It is encouraging to know that the Courts realize this, as certainly the unthinking "public" does not seem to. It would be interesting to know how many actual studies have been made of the relative cost of providing streets for parking, as against storage lots or garages for the same number of cars.

Project after project of street widening has been undertaken, presumably to provide more traffic lanes, but actually to permit Mr. Public (to say nothing of Mrs. Public) to continue his "squatter's rights" on a section of public street, and thus maintain the usual two lanes of parked cars.

Using words of Mr. McNeil: "Marginal interference is actually created by the granting of conveniences to a few at the expense of a majority." That is exactly what happens when parking is permitted on a heavily traveled street. In the future, engineers should consider the economy of providing off-street parking for the relatively few cars that can park on the street; and thus gain two traffic lanes without widening expense. Admittedly, each case will be peculiar unto itself.

Traffic engineers realize that in heavy traffic one parked car blocks a traffic lane just as thoroughly as several. For this reason a car stopping only to unload is undesirable. As a remedy for this could not loading and unloading be taken "around the corner" and off the main thoroughfare?

---

[17] Asst. Prof., Eng. Extension Service, Iowa State Coll., Ames, Iowa.

In view of the various causes of traffic delay it would seem that the traffic engineer's ideal would be a street carrying no street cars or buses, with no parking, and with "around-the-corner" loading zones. Possibly, some one may be able to "put it across." The extra width of street due to the elimination of two parking lanes would in itself stop most "jay-walking."

As regards the loading and unloading of trucks in congested traffic areas, there would seem to be only two alternatives; either handle this during the night, or provide suitable space on private property. Such regulations would probably be no more drastic than many others.

A very pertinent sentence in the paper by Mr. McNeil (see heading, "Other Remedies for Delays") is: "The engineer of a municipality should strive to improve mass transportation facilities, which in the end will decrease the use of the private automobile in the busy areas, and thus reduce congestion." Much could be done to show that there is economy and time saving in using a good system of mass transportation. By placing further limitations on parking this worthy cause could be helped. The down-town merchant should be shown that he has no cause for complaint, because many are already turning to suburban stores because of traffic difficulties. He had better face the facts and "get on the band wagon" to promote the use of mass transportation.

FRED LAVIS,[18] M. AM. SOC. C. E. (by letter).—The several papers included in this Symposium are all valuable additions to current information on this vitally important subject.

Referring to highways carrying large volumes of traffic, it is evident from the data presented that speeds of about 50 miles per hr are the maximum which should govern highway design, this being indicated both on account of safety and by economics. This also agrees with the conclusions of the writer as set forth in a paper[19] presented in 1937 at a meeting of the Highway Research Board, in Washington, D. C.

Mr. Vey's general statement that highway improvements might do away with 75% of the accidents, which now occur, does not seem to be borne out by the facts presented. Specific observations of the actions of drivers approaching certain grade crossings in Michigan, where danger signals were displayed, confirm the observations at Pittsburgh as recorded by Mr. McIntyre in the text following Table 4 and by Mr. McNeil under the heading "Remedies for Delays Due to Cross-Interference." The human element is the most important factor in the problem of highway safety, not the highway itself.

Mr. Vey's records which confirm other observations indicate that speed is an important factor both in the number and severity of accidents and, while the elimination of some of the points at which accidents occur may do away with these particular types of accidents, it seems likely that the human element, being what it is, coupled with the inducement to high speed due to the removal of some obstructions, will introduce other and perhaps worse hazards.

---

[18] Cons. Engr., New York, N. Y.

[19] "Safety and Speeds as Affecting Highway Design," Washington, December 3, 1937.

The improvements mentioned by Mr. Vey are desirable, because they will tend to increase traffic capacity and also because they will eliminate some causes of accidents. It seems very doubtful, however, even if the money was available to do all these things, that the accident toll would be reduced by anywhere near 75 per cent.

This latter statement has been widely quoted but to the writer it seems a very dangerous one to make in such an apparently authoritative manner as it tends to divert attention from the real cause of most accidents, the careless and incompetent driver. Mr. Vey himself states that the highway user (the driver and pedestrian) is responsible for the greatest number of accidents and admits that the money is not available to make all highways meet the highest engineering standards.

Mr. Vey's records of "before and after" results of improvements are, as he states, hardly sufficient to warrant anything like definite conclusions, but they do at least indicate that his optimism as to reduction of accidents by reason of such improvements, if the money were available, is not quite justified.

In regard to the economics of location, Mr. Schmidt's conclusions do not vary greatly from those stated by the writer in 1930.[20]

The writer cannot altogether agree with the definition of "traffic capacity" to which reference is made by Mr. Schmidt under the heading, "Physical Characteristics: Widths of Roadways." The validity of this definition depends on the cost of providing additional facilities for the critical speed and the value of the time saved. As in the case of most highway traffic problems, because of the very great variety of vehicles and circumstances, this problem cannot usually be disposed of so easily.

As there is little chance of sufficient money being provided to meet and overcome present and anticipated congestion, probably some sacrifice of speed will have to be made in order to provide facilities for the passage of the largest number of vehicles at such corresponding speed.

The direct assertion by Mr. Schmidt that if increased capacity is required over that provided by a two-lane highway, the change should be to a four-lane highway, is not borne out by considerable practical experience with the satisfactory operation of three-lane highways.

The increase of distance by the use of curvature does not "obviously" (see heading, "Examples"), or necessarily increase operating expenses; the alternative might be increased rise and fall. In certain types of rolling country a judicious use of light curvature may not only decrease costs of construction, but may tend to provide a more sightly highway and one which may be more pleasing and perhaps easier to drive over. Long tangents slashing across rolling to hilly country may not provide the best location if all proper factors are taken into consideration.

HUGH A. KELLY,[21] ASSOC. M. AM. SOC. C. E. (by letter).—In any paper of the same length, the writer has never seen the entire subject so tersely, yet so thoroughly, covered as in that by Mr. Vey.

---

[20] *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 1020.

[21] Civ. Engr.-Archt.-Appraiser, Jersey City, N. J.

In 1936, 36 000 souls perished by automobiles! why this annual slaughter?

In 1937, 40 000 souls perished by automobiles! why this annual increase in slaughter?

Any one who has ever stood for hours watching a parade swing by to the tunes of many blaring brass bands, will have some conception of the vastness of these numbers of deaths; 40 000 living men could not pass a given point, except "at the double," and in the very closest of formations, in less than 4 hr.

Why This Annual Slaughter?—The Engineering Profession has done much to make highway travel safe in the way of providing "fool-proof" roads and safeguards of all kinds. Daily, week-end, and holiday head lines serve to prove that the last word in safe road construction is not the solution of the problem, confronting the nation, of curbing death and injury by automobile.

Mr. Vey correctly concludes: "Because of human frailties * * *, safety on the highway is extremely difficult." However, with his other conclusion—"the impossibility of supervising and governing the actions of all persons at all times"—the writer is forced to disagree, for the following reasons:

Many years ago, he attended a meeting of the Society for the purpose of discussing the proposed Holland Tunnel. During the discussion he suggested that a physical barrier be erected in each tube of the tunnel to provide separate traffic lanes and prevent cars from crossing from one lane to the other. After thorough discussion and exhaustive research, the late Clifford M. Holland, M. Am. Soc. C. E., decided that it would not be practical to use a physical barrier; that the same measure of safety could probably be obtained by installing a painted white line down the center of each tube of the tunnel and by thoroughly patrolling each tube to see that drivers kept in line and did not cross the white line.

That Mr. Holland accomplished the results by adequate patrol (the writer had this in mind when he suggested a physical barrier), is amply borne out by ten years of safe operation, during which time, and in the face of the heaviest and most concentrated traffic in the world, there have been only two accidents involving patrons, causing three deaths, the more serious of the two accidents being caused by the illegal crossing of the white line.

Why This Annual Slaughter?—When the Pulaski Skyway, the main high-speed westward traffic artery to and from Jersey City, N. J., was first opened to traffic, trucks as well as pleasure cars were allowed to use it, with the result that the Skyway, erected at enormous cost to relieve congestion and speed up traffic in the Metropolitan Zone, became known as "Death Highway." Fatalities resulting from the careless use of the Skyway, mounted to enormous proportions. Like the Holland Tunnel traffic problems, the hazards of the Pulaski Skyway, too, were solved. The Mayor of Jersey City and the Governor of New Jersey joined forces to prohibit trucks from using the Pulaski Skyway; and Jersey City furnished adequate police officers and equipment to patrol this vital stretch of costly highway properly. Fatalities ceased, and minor accidents were reduced to a minimum.

Why This Annual Slaughter?—Is it not plain, therefore, that one of the major factors in reducing deaths and accidents on the highways—one tried and found to be successful—is proper and adequate patrol of highways?

This apparently simple solution of such a grave problem has a sound psychological basis; that is, the vast majority of drivers will, to the very best of their ability, do what is right and proper, and the malicious or careless minority will fall in line when they are positively certain, as they will be under a patrol plan, that they are being watched carefully, and will positively feel the heavy hand of the law for failure to comply strictly with reasonable traffic rules.

Therefore, the writer proposes that a highway patrol be organized, that the highways be patroled 24 hr per day, that a man be assigned to such areas as he can control—which in congested districts may be not more than a half mile. A distinctive uniform to be worn at all times while on duty, and a flood-lighted car or motorcycle at night, should be provided, so that law-abiding citizens and others shall be under no misapprehension as to the penalty for failure to observe the rules of the road.

Another matter that has not been given the attention it should receive, is one that the writer presented to the State Highway Department of New Jersey many years ago; that is, to eliminate the great hazards of night driving by properly illuminating the highways.

Why This Annual Slaughter?—Motorists, of all citizens, are the taxpayers par excellence, and the public should be selfish enough to keep them alive and free of injury for their continued ability to pay taxes, if for no other reason. The writer feels that no increase in taxation is needed to give effect to this proposed plan of proper and adequate highway patrol. Ample funds are now provided by the car-owning and driving taxpayers *via* gasoline taxes and license fees to take care of the increased personnel necessary to do away with this wanton destruction of life and property.

This is the only manner in which this blight may be removed forever from the highways of the United States and this is a solution far simpler than the sending of careless drivers to morgues, and the reading or memorizing of "horror" tales based on destruction of human life by automobiles, and other sincere but vain efforts to bring about the same result.

Why This Annual Slaughter?

SIDNEY J. WILLIAMS,[22] M. AM. SOC. C. E. (by letter).—In commenting on this Symposium, in general, the writer can only commend the thorough and sound analyses of the various papers presented. More States and cities should make these accurate detailed studies of how traffic moves and how accidents occur. Such data are the only sound bases for efforts, both national and local, to reduce accidents and congestion.

One subject, briefly alluded to in these papers, deserves further discussion, namely, pedestrian hazards, pedestrian protection, and pedestrian control. The streets and highways, traffic control equipment, and traffic control by police have been devised almost entirely to expedite and protect vehicular traffic. About 40% of the persons killed in motor vehicle accidents in 1937 were pedestrians. In cities alone the percentage is about 67, and, in large cities, it is even greater. Pedestrian deaths in cities have been reduced slightly since 1930, but have increased 64% in the rural districts.

---

[22] Director, Public Safety Div., National Safety Council, Chicago, Ill.

How is this problem being met? Many persons advocate laws requiring the pedestrian to observe traffic signals, although, with a few notable exceptions, the signals were not designed for that purpose and take no account of the speed limitations of the pedestrian. They try to "educate" pedestrians chiefly by telling them to keep out of the way of vehicles, to cross at cross-walks, and with the green light, but with little corresponding "education" of the drivers to give the pedestrian "a break" when he does try to cross at the corner and with the green light.

The City of Pittsburgh has done far more for the pedestrian than most cities, yet even Mr. McNeil, in referring strictly to his topic of relieving traffic concentration, cites the considerable delays to vehicles caused by pedestrians, but mentions nothing of the enormous delays to pedestrians caused by vehicles. He suggests only "rigid enforcement of the laws eliminating jaywalking and confining pedestrian crossings to the intersections." This proposal is entirely correct, but with it must go equally rigid enforcement of the laws that give the pedestrian the right of way over the vehicle if the former is crossing at an intersection where there is no traffic control, or if he is crossing or has started to cross with a green light.

Actually, most vehicles turning on a green light do not yield any right of way to the pedestrian crossing on the same light, and most vehicles start instantly on the green light (if not before) with no regard for pedestrians who have started to cross and are thus left stranded in the middle of the street. Is it any wonder that under these circumstances many pedestrians feel they can place no reliance on the "protection" of the law or the courtesy of the driver and are thus tempted to depend entirely on their agility and dash across wherever and whenever they can see an opening in the traffic?

The writer does not intend at all to deny that a great many pedestrians are inexcusably careless and that all efforts to educate them out of this habit must be continued. He maintains only that, along with this, the engineer and the police officer must give much greater consideration to the pedestrian than most of them have done in the past. The engineer can help the pedestrian by providing raised loading platforms at street-car stops, and other safety islands in the center of wide or very busy thoroughfares, adequate sidewalks along rural highways traveled by pedestrians, and special "walk" signals where the volume justifies. Police departments can give more attention to requiring drivers to observe the legal and moral rights of pedestrians at crossings, as well as dissuading the latter from careless practices and in extreme cases arresting them. Educators, especially of the adult public, can study the entire problem more closely and can apply "selective education," which means determining the social and geographic groups that suffer the most pedestrian accidents and reaching them through appropriate channels.

The problem is well summarized by the following quotation:[23]

---

[23] Rept. of the Committee on Pedestrian Control and Protection, National Safety Council, 1937.

"In approaching the pedestrian problem it ought to be recognized that, except in a few cases of suicide, pedestrians do not want to be injured or killed in traffic. It should also be admitted that drivers do not want to be injured or killed in traffic. It should also be admitted that drivers do not want to injure pedestrians. Accidents occur where unexpected conditions arise, or traffic becomes so complex that normal walking habits and ordinary precautions do not supply the necessary protection."

Harold Nevin Carey,[24] Esq. (by letter).—Some questions concerning the economic justification for expenditures for highway improvements are raised by Mr. Schmidt. He emphasizes the commonly accepted proposition that a shortening of highway length results in a savings to the individual motorist, and hence to the public in general.

Without raising the question of the proper data to use for the cost of operating an automobile, or whether any value can be claimed for savings in time, one should consider the effect on the expenses of one automobile driver of a reduction in highway length of a quarter of a mile.

The items of operating cost that may be said to be affected to any extent by the distance traveled are those for fuel, lubrication, tires and tubes, maintenance and, possibly, depreciation (see Table 13). What is the effect on these factors of shortening the distance traveled by the quarter of a mile?

Fuel.—The saving in fuel would be the sum necessary to drive a quarter of a mile, perhaps (on a basis of 15 miles per gal) 1/60 gal, or a little more than 2 oz. At 20 cts per gal this would represent 1/3 ct. It is doubtful, however, if the driver has saved that 1/3 ct when there are so many other factors affecting gasoline consumption—the adjustment and condition of the motor, the operation of the choke, and the speed of driving (a change of driving speed from 25 to 50 miles per hr may make as much difference as 4 miles per gal with a light car), whether the driving is continuous or stop and go, etc. It scarcely seems that a savings of that 1/3 ct can be claimed for the driver, inasmuch as the next month or the next day a varying combination of conditions may waste more than the "saved" 2 oz of gasoline.

Lubrication.—Regardless of what data are used for miles per gallon of oil or per pound of grease, there would seem to be no monetary savings to the driver due to the quarter of a mile saved. The distance traveled has little influence on these values in comparison with such factors as whether the driver remembered to change oil at 1 500 miles or at 1 800 miles, or whether he took the car down to be greased three, four, or five times in 10 000 miles of driving.

Tires and Tubes.—In this case, again, there will be no monetary savings to the driver due to the quarter of a mile saved when his tire cost is almost entirely governed by the time when he decides to replace his tires, because tires are not used until they are absolutely worn out. A decision to buy new tires this Monday instead of next Friday has such an influence on costs as to overshadow, entirely, a saving in driving distance of a quarter of a mile.

Maintenance.—On the record, the fact that the driver did not cover the quarter of a mile could scarcely save him any money on maintenance expense.

Depreciation.—Here, again, the distance traveled has a relatively small bearing on the final depreciation cost to the driver because that is determined mainly by the time when he decides to turn in the car. Therefore, the saving in distance results in no monetary savings.

---

[24] Civ. Engr., Ayres, Lewis, Norris & May, Ann Arbor, Mich.

From the foregoing it would seem that it cannot be shown that, as far as the one driver is concerned, there has been any actual monetary savings due to the shortening of the distance traveled by a quarter of a mile.

The economic justification for highway expenditures based on a shortening of the distance is customarily computed by multiplying the mileage saved by the assumed affected operation costs per mile for one car and, taking this figure as the savings per car, multiplying by the annual number of cars to give the total annual savings; but if it cannot, definitely, be shown that one driver actually saves anything by the shortening of the distance, how can he be multiplied by a legion to obtain anything? Zero times *n* is still zero.

W. W. Crosby,[25] M. Am. Soc. C. E. (by letter).—The writer's interest in the paper by Mr. McIntyre prompts the following questions:

What degree of betterment to the speed of through traffic would result from "rotary" instead of right-angled intersections?

What reduction of speed would result from "weaving" through a rotary intersection of rational diameter?

What progress has been made, and with what results on the congestion in down-town Pittsburgh, through the diversion of through traffic over the "Belt Roads"[26] around the city?

Referring to Mr. McNeil's paper the writer offers the following: His experience convinces him that many present traffic difficulties come from too narrowly weighing an improvement "from the standpoint of cost *versus* benefit to business" (see "Synopsis"). Genuine economy is a high ideal, but "benefit to business" is too mean a "yardstick." Elasticity of results, that is, the capacity for adjustment to changes in demands, convenience, and even human pleasure, is also part of the functions of highways. Mr. Schmidt refers to this under the heading, "Highway Economics."

"* * * grade separations are decidedly expensive * * *" (see heading, "Remedies for Delays Due to Cross-Interference," in Mr. McNeil's paper), and as Mr. McNeil suggests, many could be avoided (by rotary intersections, for instance) had the "elbow room,"[27] that is, wide right of way, been acquired in advance. It must be remembered constantly that the road of to-day is the street of to-morrow.

Pedestrian under-passes, unless unavoidable, will not prove efficient when they are built with steps. To encourage their use to the maximum benefits, ramps are obligatory.

Good results have been obtained in many places by requiring pedestrians, as well as vehicles, to obey traffic signals. One difficulty sometimes yet remains (referred to by Mr. McIntyre following Table 5) that of vehicular turns through "pedestrian traffic moving parallel with the traffic stream." It has been met, to some benefit, by permitting vehicular turns to the right on the red light.

---

[25] Col., U. S. Army (*Retired*); Cons. Engr., Coronado, Calif.

[26] "Highway Location," by W. W. Crosby, Gillette Pub. Co., 1928, p. 127.

[27] *Roads and Streets*, October, 1934, p. 362 *et seq.*

Mr. McNeil states (in the paragraph preceding "Remedies for Delays Due to Medial Interference"): "It is not practicable, however, to confine any street to one-way traffic." One wonders if, for instance, the authorities of New York City would agree. He states further (see heading "Other Remedies for Delays") in effect, that an individual using his private car "spends several times the money that he would in using a mass-transportation vehicle." This situation is one to be faced squarely by highway engineers, even if deplored. He also states that unless a by-pass has certain characteristics it will fail. The writer would enlarge the list of characteristics by adding that it must have the width, or other means of protecting its flanks, sufficient to prevent an early demand for by-passing the by-pass.

Mr. Schmidt (see heading, "Highway Economics: Traffic Considerations") thinks the ownership of automobiles "surely must be approaching a 'point of saturation'." It might be well to consider the suggestions made by such an eminent authority as Frederic Law Olmstead who, in 1926, implied, that "The Saturation Point (of automobiles on roads) might depend greatly on the time available to people for using them."[28] If working hours per week become less, the writer sees no prospect for a saturation point to be reached in the near future, especially when other factors, such as the "more abundant life" and "higher standards of living," etc., are considered.

The writer wishes to commend many of the statements of the various authors in this Symposium, particularly those as to divided roadways, service ways, the elimination of parking on through-ways, the by-passing of through traffic, the use of ample diameter for circles or rotary intersections, the location of entrances to parking spaces, larger curb radii,[29] loading lanes (such as that of Stern Brothers' Department Store on 43d St., in New York, N. Y.), the "channelization" of roadways, and the desirability of a sufficient width for the "islands" or divisional strip so that turning-traffic dangers may be minimized.

ROGER L. MORRISON,[30] M. AM. SOC. C. E. (by letter).—Of the many items discussed in the Symposium the most controversial are probably those relating to economics.

In estimating the cost of motor-car operation Mr. Schmidt uses data which were determined a number of years ago and these costs are now probably too high. A friend, who drives approximately 35 000 miles each year, kindly gave the writer detailed operating cost data on five cars of the same make which he used between January, 1927, and November, 1935. The records show a constant decrease in cost from 5.53 cts per mile on the first car to 2.80 cts per mile on the last one.

Another point, apparently not considered in Mr. Schmidt's paper, is that if the average cost per mile for gasoline, lubrication, tires, maintenance, and depreciation is, say, 3.1 cts per mile, that does not mean that a saving of 1 mile in distance gives a saving of 3.1 cts per car. The average per-mile cost of gasoline includes that used in starting and stopping, standing with motor running, and driving many short distances with a cold motor, none of which is involved, as a rule, in driving an extra mile on a trip. Furthermore, the average per-mile cost of tires includes deterioration from time, weather, injuries, and excessive use of brakes, which are not appreciable in driving an extra mile. Of course, no one knows just how much should be deducted to cover these items, but 2.5 cts per mile for passenger cars would probably be as large a value as should be used in computing savings in operating costs due to decreased mileage.

---

[28] Rept. No. 39, to 5th Congress (Milan, 1926), Permanent International Assoc. of Road Congresses.

[29] "Improving Street Corners," *American City*, November, 1930, p. 140.

[30] Prof. of Highway Eng. and Highway Transport, Univ. of Michigan, Ann Arbor, Mich.

Many laymen, and some engineers, are inclined to adopt a rather contemptuous attitude toward the small per-mile savings used in the computations of highway economists. The writer has often heard it stated that such savings are too trifling to be worth considering; but in this connection it should be remembered that a gasoline tax of 1 ct per gal amounts to only about 1/15 ct per mile, and the writer has neither seen nor heard any statements that such a tax is too small to be considered. On the contrary, many a bitter fight has been waged over that particular 1/15 ct per mile.

W. R. FLACK,[31] ASSOC. M. AM. SOC. C. E. (by letter).—The most important and often the most neglected aspect of highway design is that treated in the valuable and interesting paper by Mr. Schmidt. Although the subject matter is somewhat removed from the general theme of the Symposium, the writer is most particularly concerned with the section on "Costs and Savings," which analyzes the financial investment in highway construction. One of the governing factors in such an analysis is the operating cost per mile assigned to the typical vehicle. Believing the study of this important problem might be advanced by the collection of more data, the writer desires to submit some original findings on the costs of owning and operating passenger automobiles. In Table 16, Car 1 was a 1931, two-door sedan; Car 2 was a 1931 coach; and Car 3 was a 1936 model of Car 1. Mr. Schmidt cites the studies made by Dean Agg and Professor Carter,[14] in 1928, and by Mr. Johannesson,[15] in 1931. The writer's data are based on a record of costs that began in March, 1932, and is continued to January, 1938. The values are so at variance with Mr. Schmidt's estimate that a detailed itemization and description are in order. The values shown in Table 16 are cents per mile.

These cars were owned and operated in Medina County, Ohio. The average annual mileage was 11 900. About 95% of these miles were on pavement. The values for depreciation are actual for the first two cars, and those on the last car are an appraisal made from advertised prices of used cars. The garage rent is a somewhat arbitrary estimate, and is open to the question of whether it should have been included at all; nearly all houses in the vicinity had garages, and it is difficult to find a tenant for an empty garage; it is necessary for a house tenant to pay rent on a garage whether or not he has a car. The license includes tax; there are no other property taxes levied on cars in

---

[31] With The Babcock & Wilcox Co., Barberton, Ohio.

Ohio except that contained in the cost of the license; this item also includes the driver's license. The insurance covers fire, theft, property damage, personal liability, and, in 1937, collision; there was no insurance in 1932. Gasoline (various brands) was purchased retail. Oil was usually bought in 5-gal lots and added as needed; changes were made about every 4 000 miles.

TABLE 16.—COMPARATIVE COSTS OF OWNING AND OPERATING PASSENGER AUTOMOBILES, IN CENTS PER MILE

Description	Car 1, March, 1932, to March, 1934	Car 2, March, 1934, to August, 1936	Car 3, August, 1936, to January, 1938	All cars entire period	Description	Car 1, March, 1932, to March, 1934	Car 2, March, 1934, to August, 1936	Car 3, August, 1936, to January, 1938	All cars entire period
Depreciation	0.559	0.701	1.186	0.801	Greasing	0.033	0.024	0.056	0.036
Garage rent	0.365	0.364	0.187	0.309	Tires	0.090	0.103	0.004	0.068
License	0.060	0.063	0.086	0.069	Batteries	0.047	0.041	....	0.031
Insurance	0.133	0.326	0.239	0.231	Parking	0.045	0.068	0.037	0.050
Tools	0.019	0.005	....	0.009	Alcohol	0.015	0.013	0.017	0.015
Equipment	0.022	0.084	0.064	0.056	Bridge tolls	....	....	0.014	0.004
Gasoline	0.998	1.373	1.180	1.176	Fine	0.033	....	....	0.012
Repairs	0.295	0.152	0.003	0.156	....	....	....	....	....
Oil	0.116	0.058	0.081	0.086	....	....	....	....	....
Total	....	....	....	....	....	2.830	3.375	3.154	3.109
Miles	....	....	....	....	....	24 158	23 118	21 090	68 366

No item is included for interest. These cars were regarded as necessities, and over some periods were absolutely required for the owner to reach his employment. The existence of a question as to whether or not to own a car was not recognized. A corporation may sell bonds and assume the expense of the interest on them when raising the capital for an improvement or addition to its property. It is difficult to understand how this procedure can apply to an individual in the purchase from income of what he regards as a necessity. Furthermore, as Harry J. Engel, Assoc. M. Am. Soc. C. E., has stated:[32] The theory about capital that saved money somehow automatically deserves to earn interest compounded at 6% is not well supported by the facts.

These costs are subject to adjustments to eliminate peculiarities of the conditions and to conform to more generally accepted accounting methods. The record of out-of-pocket spendings is complete and accurate.

The net operating cost per mile should include the following items from the costs given in Table 16:

Item	Cost, in cents per mile
Gasoline	1.11
Repairs	0.16
Oil	0.09
Greasing	0.04
Tires	0.07
Batteries	0.03
Total	1.50

---

[32] "Social Horizons for the Engineer," by Harry J. Engel, *Civil Engineering*, November, 1937, p. 763.

These are the only items that will be affected directly by any reduction of distance. The gasoline cost has been reduced; the sum given in the record included considerable "stop-and-go" winter driving of the kind in which a mother takes the car out on especially cold mornings to drive the children a mile to school. This service is performed at a cost of gasoline the economist has no right to consider in examining highway relocations. Data on gas consumption, considered as a function of the distance driven per month, showed a remarkable consistency; the miles per gallon equalled about $12.00 + 2.66 \left(\frac{\text{miles driven in month}}{1\,000}\right)$. The months of low mileage per gallon and few miles per month were in the winter when starting required more than the average quantity of gas. The fact remains that the road designer is concerned with a car—or a million cars—rolling on the pavement, not as it moves, choked, in reverse gear from the garage to the street. The cost of repairs might also have been reduced, as some of the breakages had no relation to distance traveled. However, this owner was probably more fortunate than the average.

It seems to the writer that an analysis of total cost should be based upon a minimum value for the expense of vehicle operation; one should not attempt to make an economic justification of highway expenditures based on operating costs of inefficient, luxurious, or carelessly operated vehicles. As to estimating future savings, it is likely that advances in drainage, soil mechanics, design of Portland cement and bituminous concretes, and the performance of automobiles will make anticipating economies beyond a period of, say, fifteen years, imprudent. The designer might be on better ground to describe his relocation as one that would be paid for in savings to drivers over a term of fifteen years than to claim that the cost of the proposal is an equivalent 6% capitalized cost. The results of the two methods might be the same, but the vehicle costs can be estimated much more accurately than the interest the money might have earned.

The cost of vehicle operation may be used in estimating the expense to the public of detouring a project during construction. The writer knows of one badly timed project during which the additional operating cost of the traffic making the detour amounted to at least 30% of the cost of the construction. If this factor had been recognized some other design would certainly have been used.

HAWLEY S. SIMPSON,[33] M. AM. SOC. C. E. (by letter).—The clear analysis of the highway accident situation, presented by Mr. Vey, throws needed light on a subject of major importance. Of particular interest was his discussion of the accident experience on two-lane and four-lane highways in which he casts considerable doubt on the often reiterated theory that "congestion breeds accidents."

His data indicate that the reverse may be true when he shows that two-lane roads carrying more than "capacity" traffic have less accidents on a usage basis than when travel is lighter. Probably, however, the limited number of opportunities to make observations on the more heavily traveled two-lane roads makes data for them of somewhat less reliability than where more samples were obtained.

---

[33] Research Engr., Am. Transit Assoc., New York, N. Y.

Furthermore, four-lane roads are shown to have a greater accident expectancy than narrower pavements. This is probably due partly to the fact that the per lane usage of the four-lane roads is less than that of the two-lane roads, so that, as Mr. Vey states, the individual motorist is allowed greater flexibility of movement, which always leads to higher accident rates. It is quite probable that if New Jersey's four-lane roads were carrying as much traffic per lane as the two-lane roads, the accident rates per vehicle-mile on the two types would not differ greatly. If this conclusion is even approximately correct, it is obvious that there is little to be gained, from the standpoint of highway safety, from the customary types of highway construction, regardless of width.

Consequently, the natural conclusion is that, unless substantial changes can be made in the aptitudes and attitudes of the driving population, which is most unlikely, safety can only be promoted by the construction of highways that will make it impossible for many types of accidents to occur.

That the expected reduction from this higher type construction will reach 75% seems to be unwarranted on the basis of available data. Although it is true that the highway which physically segregates the more important conflicting traffic flows would undoubtedly largely reduce certain types of accidents, there is as yet insufficient experience to indicate the extent to which other types of accidents may be increased in volume and perhaps even in seriousness. By removing all, or substantially all, apparent hazards, motorists may, on these new roads, be lulled into an entirely false sense of security and, therefore, attempt to obtain from their vehicles more nearly the maximum speed built into them. Thus, drivers may unconsciously be led into accident-provoking situations, which they cannot, or do not, recognize until it is too late. In the higher range of speeds the ability of an individual to control an automobile decreases as the speed increases, resulting in a lessened margin between safety and accidents. If this is carried far enough, the accident toll, instead of being appreciably reduced, may be only slightly affected. On the narrow, winding, and congested roads on the other hand, the many apparent hazards induce drivers to exercise an extreme degree of caution and so to compensate, or even over-compensate, for these hazards by extra careful and prudent operation.

There are certain comparatively inexpensive measures, however, which could, if more widely used, create appreciable improvement in accident experience without such great expenditures of money as would be required to produce the "fool-proof" highway. Two of these are particularly important—highway lighting and rural sidewalks.

At speeds of the order common on rural highways, automotive headlights provide wholly inadequate pavement lighting. There are numerous limitations that seem to lie in the way of looking to the vehicle, itself, to provide sufficient light for night operation at speeds to which drivers are accustomed during the day. For a relatively small percentage of the cost of highway construction, adequate lighting can be furnished. Mr. Vey has already made studies of the effect of highway lighting on accidents and has found an economic saving in every instance. Although highway lighting is not as spectacular as the construction of high-speed, grade-separated highways, and, therefore, does not attract as much attention, economic considerations suggest that a greater proportion of highway funds be put into lighting than in the past.

Highway sidewalks, now practically non-existent, should be constructed along every mile of heavily traveled rural highway. They should be so attractive that the pedestrian will wish to use them in preference to the paved roadway. Pedestrians, as a group, have suffered greatly from the automobile; yet little attempt has been made to provide facilities that will enable them to move about with dignity and safety.

More analyses of the kind conducted by Mr. Vey, in New Jersey, should point the way to the development of a highway system with a balanced consideration of all the numerous factors involved.

CHARLES M. NOBLE,[34] M. AM. SOC. C. E. (by letter).—Highway engineers should welcome Mr. Vey's excellent paper since it presents an analysis of the value of highway improvements based on actual accident records in a State small in area but with a heavy concentrated population. The area lies between the largest city and the third largest city in the country, and forms part of a cluster of States containing less than 4% of the area and more than 25% of the population of the United States. Indeed, New Jersey is known as the "Highway of the Nation." Certainly the accident experience in such a State should include a sizable proportion of the total vehicle-miles operated in the United States and should be representative of present-day congested traffic conditions as well as indicative of future trends in the less congested regions.

It is somewhat strange that highway engineers should have neglected making an appraisal of the value of each type of highway improvement from the standpoint of the accident experience of the user of the highway, particularly since it is an essential function of the engineer to deal with well substantiated facts in the design of engineering structures. It would appear axiomatic that the designer should provide a structure as ideally suited to the use that will be made of it as is practicable. The paper by Mr. Vey is a start in this direction which should prove an incentive to highway organizations to continue this form of statistical analysis in order that the use value of each type of design may be more clearly defined, and to establish its economic value. The inherent safety and "accident-proof" qualities of a design should be thoroughly established by actual tests and records before the engineer expends large sums on its construction. A design that develops a bad accident record will not reflect any credit on the designer and, in addition, it will create the impression among laymen that the engineer is either not fully alive to his responsibilities or that the problem is incapable of an engineering solution. Either conclusion would be disastrous to the highway engineer and the highway transportation industry.

The business depression years have produced a feeling among many classes of people that the highway system of the nation has been completed to as large an extent as required and that the sums collected from the motorist in the form of gasoline and oil imposts should be diverted to unemployment relief or for other governmental purposes. Indeed, large sums have already been diverted from highway funds, and some of the philosophy behind such diversion may be traced to this idea. Even among engineers the measurement of adequate highway transportation service has been computed, in the past, on the mass basis of mileage and the condition of the roadway surface rather than from the quality standpoint of the safety, comfort, and convenience of the user. Design which provides inherent safety for the motorist is distinctly a new trend. Mr. Vey's paper presents accident facts to support this trend and to substantiate the engineer's conviction that henceforth the "measuring stick" must be quality and not quantity; and, furthermore, that the country is not overbuilt but, on the contrary, that it is in urgent need of all the funds collected from motorists to modernize the existing highway system as well as to construct new trunk routes and farm-to-market roads.

---

[34] Engr., Pennsylvania Turnpike Comm., Harrisburg, Pa.

It is stated that the data in the paper were derived from statements filed by the participants in accidents, with supplementary notes, in some cases, by the State Police. It is recognized, of course, that this type of data will reveal only the most rudimentary causes of accidents and will merely serve to classify the general type of accident. Mr. Vey recognizes this and rightly only attempts to utilize the latter information. The more subtle causes cannot be brought forth by participants, since it is scarcely possible for them to recognize such causes. All too often a particular set of conditions in or surrounding the highway combine to cause the motorist to commit an error in judgment which with lightning-like rapidity climaxes in an accident; and thus it is quite possible that more accidents are caused by defects in highway design than are indicated in the paper. Nevertheless, it is interesting to analyze the information in Fig. 5 and list the percentages which certainly can be almost wholly prevented by perfected highway design; and to speculate on the approximate percentage of reduction of those types which one cannot state with absolute certainty will be wholly eliminated.

Referring to Fig. 5, it is noted that 14% of all accidents are of the right-angle type at intersections, and that 1% occur between intersections. If grade separations are constructed at all crossings with proper acceleration and deceleration lanes this first type of accident should be completely eliminated—namely, 14% of all accidents. In the case of opposite direction left-turn accidents, those occurring at intersections will also be eliminated by grade separation, namely 5 per cent. In the case of pedestrians, if their presence is removed from the motor areas and provision is made for them elsewhere, this type of accident can be almost entirely prevented; and it is safe to state that all but 2% of the total can be eliminated, namely 8 per cent. The opposite-direction accident can be eliminated by the provision of a wide space separating opposite-direction traffic, accounting for a total of 21 per cent. If all fixed objects are removed for a reasonable distance from the pavement, the fixed-object accident can be largely prevented; but in order to be conservative it may be assumed that surely one-half these accidents can be eliminated, namely 6 per cent. Many types of same-direction accidents are caused by the influence of oncoming opposite-direction traffic, and if the divided highway principle is utilized, this type of causation is eliminated. Furthermore, the use of curbs that hamper lateral freedom has an effect on this type of accident because the motorist does not have the opportunity to dodge sidewise on to the shoulder to avoid a crash in case of an emergency. Wide, smooth, stabilized shoulders, level with the pavement, permit lateral freedom and will have a favorable influence on same-direction accidents. If divided design and wide shoulders are utilized, and if it is assumed that one-half the same-direction accidents will be eliminated between intersections because of such design, then it is probable that 10% of all accidents will be prevented. The same-direction accident at an intersection is caused by the stopping of vehicles at traffic lights or slowing down or stopping to make a turn. If grade separation is utilized with acceleration and deceleration lanes these accidents will be eliminated, namely, 10% of all accidents.

To summarize, the use of known design technique will surely eliminate the following types and percentages of accidents: Right angle, 14%; opposite direction left turn, 5%; pedestrian, 8%; opposite direction, 21%; same direction at intersections, 10%; giving a total of 58 per cent. If the probable reduction of fixed object accidents (6%) and same direction between intersections (10%) is added the total becomes 74%, which is a very close check on Mr. Vey's statement of 75 per cent. Thus, it can be seen that improved engineering technique and design will have a pronounced favorable effect on accidents.

In addition to the savings resulting from the foregoing general features of design, it is very possible to reduce the accident toll still further by close attention to highway details in order that all features will conform to the requirements of the user and may be as accident proof as possible. Mr. Vey recognizes the entire problem very clearly, summing it up concisely in his paper as follows (see heading "Synopsis"): "It is necessary that roadway facilities be designed and applied, which are inherently safe, as far as possible, in order to render the failures of human beings of lesser or little importance."

The vehicle-mile basis of comparing accident experience presents a rather accurate method of measuring comparative conditions between various general types of highways, and it is hoped that properly designed automatic recording stations will be established generally in order that such comparisons may be more widespread and that accident statistics may be compared on a more accurate basis than at present. In comparing various individual design features it may prove more illustrative, however, if some kind of rating could be established whereby each different design of the same type would be classified as being a certain percentage of a perfect, or 100%, score. In this manner, definitely bad design would very quickly score a low rating in comparison with other types of design and, being based on actual accident statistics, such a method would be of immense value in establishing correct design as well as furnishing unassailable proof to governing authorities of such good design.

The statement made in the paper that 59.6% of State highway accidents occur between intersections and 40.4% at intersections, and (see heading "Accident Location and Time of Occurrence") "that the sections of State highway having little or no cross-movements of traffic are the more hazardous" may cause some misconception of relative accident exposure. The statistics are undoubtedly correct, but it must be remembered that the actual space occupied by intersections on State highways is much less than the space traversed by a vehicle between intersections. Thus, the unit of exposure to accidents based on distance traversed, on time, or per vehicle-mile, or on any other basis of actual comparison, is much greater at intersections than on the comparatively long stretches between. As a crude illustration: If it is assumed that each intersection is 100 ft wide and that intersections are 1 mile apart, it will be thirty-six times more hazardous to traverse each foot of intersection than each foot of open highway between intersections.

It is frequently stated that each year only 15% of the drivers are the cause of 90% of all accidents, and the inference is that if these 15% were eliminated from the highways the accident problem would be solved without having to make any further improvements in the present highway system. It is true that 15% of the drivers cause a large percentage of the accidents each year, but, unfortunately, it is not the same 15% every year, except for a small percentage of accident-prone drivers who are known as "accident repeaters." If it were true that the same drivers were involved in the majority of accidents year after year they would soon destroy themselves and the accident problem would have solved itself long since, without any exertion on the part of the engineer. This suggests that the average driver is involved in the greater number of accidents—motorists who are sober and substantial citizens. In addition, the experience to date indicates that the behavior of the driver is the most difficult element in the situation to control, whereas the design of the highway can unquestionably be controlled with any degree of accuracy required. It would appear, therefore, that full use should be made of this fact, and that all the known safeguards should be incorporated in the design to as great an extent as is economically justified in order to overcome the weaknesses and mistakes of the user.

The situation is similar to the conditions existing in industry some years ago when workmen were not protected from moving machinery and other hazards by proper safeguards, and, consequently, the industrial accident toll was quite high. At that time accidents were assumed to be an unavoidable evil and part of the risks of manufacturing, little effort being made to improve the situation. Then, as to-day in the motor field, the operator of the machine was assumed to be at fault in case of injury, the assumption being that he was inept or careless. The tremendous reduction in industrial accidents by the use of proper safeguards is an indication of the results possible when the problem is attacked with the proper mental attitude and with vision and courage. Thousands of men and women are alive and well to-day who would be dead or permanently disabled had it not been for that effort. A similar opportunity exists for humanitarian service in the motor accident field; and since, in contrast with the industrial accident problem, the highway user will pay the cost of such safeguards, he is entitled to the most perfect product which knowledge and skill can produce.

The facts and figures given by Mr. Vey form a powerful tool which highway engineers should be quick to seize in order to prove conclusively to laymen and officials that highway improvements are a vital and effective means for combating the accident problem, that the need for such improvements is imperative if the accident disease is to be checked, and, furthermore, that diversion of gasoline and oil imposts is causing the death and injury of thousands of human beings yearly. Therefore, Mr. Vey is to be congratulated on his valuable paper, and it is hoped that it will create an incentive to highway authorities to continue and extend this form of analysis in order to establish authoritatively the theory that improved highway design is a fundamental need.

LEWIS W. MCINTYRE,[35] M. AM. SOC. C. E. (by letter).—The primary purpose of this paper was to record, for the use of other engineers, certain factual data concerning the actual movement of city traffic. Although these data were obtained possibly as long ago as 1928, for the purpose of establishing whether a signal system could be used in down-town Pittsburgh, they have been found useful in comparing the traffic capacity of various plans for separation of grades, for bridge plazas, traffic by-passes, etc. In a number of cases, the decision as to which of a number of suggested plans should be selected has depended on an analysis of traffic capacity based on these data.

To the best of the writer's knowledge, no similar data have been published. The technique for determining traffic capacity, which has been developed from these data, has been found extremely useful. It is hoped that other engineers may also find the data of service.

ARNOLD H. VEY,[36] ESQ. (by letter).—In this closing discussion, it is the writer's intention to discuss the comments expressed by Messrs. Lavis, Kelly, and Simpson, all of whom more or less took the writer to task for the optimism he expressed concerning the favorable reduction in accidents which might be expected following major highway improvements.

Mr. Lavis states that the statement to the effect that highway improvements might do away with 75% of the accidents which now occur "does not seem to be borne out by the facts presented." Mr. Simpson makes the same general statement and uses the words "seems to be unwarranted on the basis of available data." Colonel Kelly is of the opinion that safe road construction is not the solution of the problem and disagrees with the conclusion, contained in the original paper, as to "the impossibility of supervising and governing the actions of all persons at all times." Mr. Lavis considers the real cause of traffic accidents to be the careless and incompetent driver.

The driver, of course, is the cause, and upon him can be placed the largest share of responsibility. After all, of the three elements concerned—the highway, the car, and the highway user—he is in control of the movement of the vehicle; and, too, he shapes the path of the vehicle along the public highways. Therefore, if all highway users were perfect and at all times drove in a manner having regard for the conditions of the vehicle as well as highway conditions, all would agree that there would be no traffic accident problem. However, when indicting the highway user as the element of greatest responsibility, it is necessary to consider all highway users and not any one particular class or group as Mr. Lavis advocates.

It is true that in any one year, a rather small proportion of the licensed drivers (ranging from 10% to 15%) are involved in all the accidents of that year. Unfortunately, however, with few exceptions, the citizens identified in this small group are not responsible for the highway ills year after year. If this were the case, the solution would be rather simple as it would not be difficult to identify these accident breeders quickly and either correct their habits or remove them from the roadway entirely by revoking their driving privileges.

---

[35] Traffic Consultant, Pittsburgh, Pa.

[36] State Traffic Engr., Div. of Traffic Control and Regulation, State Dept. of Motor Vehicles, Trenton, N. J.

Those involved in motor-vehicle accidents come from all walks of life. For the most part, the accident problem concerns average, law-abiding citizens, many of whom have driven for a number of years and have never before had an accident and, of course, who did not intentionally drive in a manner to cause an accident.

The solution of the motor-vehicle accident problem, despite the complication of causes, can be summed up in two words—"safeguards" and "safe practices"; that is, the application of adequate and appropriate safeguards and the performance of safe practices on the part of highway users.

Safeguards include the construction of highways that are inherently safe—highways that render the failures of human beings of lesser or little importance; and, highways that make it less possible for drivers to perform improper practices, causing accidents. Unfortunately, there are only a few examples of such types of construction in the United States. However, there are many examples of parts of a highway embodying all of the principles and features in one form or another but not confined to, and along, the same section of roadway.

An indication may be had, however, of the probable reduction in accidents through such highway improvements by reviewing accident experience along present-day roadways and determining, from such an analysis, the percentage of accidents that might be eliminated had the roadway system embodied all of the present-day safeguards known to the highway engineer.

For example, the accident experience along the New Jersey State Highway System over a period of one year was segregated into the various types of accidents and further separated by their place of occurrence—whether at or between intersections—and the following distribution was shown:

Type of collision	Percentage of accidents at intersections	Percentage of accidents between intersections
Right angle	14	1
Same direction	10	20
Opposite direction (head-on)	3	18
Fixed object	2	9
Pedestrian	4	6
Opposite direction (left turn)	5	1
Other types	2	5

Reviewing the foregoing tabulation, it is apparent that by controlling the right of way (prohibiting acess to abutting property as well as eliminating all cross traffic at grade), mostly all right-angle and opposite-direction (left-turn) types, as well as pedestrian accidents—all of which aggregate 31% of the total—would be eliminated.

The center island, segregating opposing flows of traffic, would prevent nearly all head-on collisions which comprise 21% of the total; fixed-object accidents, equaling 11% of the total, would also be curtailed through the elimination of fixed objects within the travelable part of the highway, together with the elimination of fixed objects adjacent to, and along, the traveled way.

The classification "same direction" concerns three more or less common types of collisions involving vehicles traveling in the same direction—"rear-end," "cutting-in," and "side-swipes." Of these three, the first is by far the most common. Although there has not yet been developed a practical physical means of dealing effectively with accidents of this type, particularly those occurring at between-intersection locations, nevertheless it is the opinion of the writer that the type of highway improvement with which this discussion is concerned would not only correct most of the same-direction accidents that now occur at street intersections but would also affect, favorably, the same-direction accidents that occur between intersections. Furthermore, the application of proper and adequate highway lighting would curtail night-time accidents effectively, particularly those of the same-direction type, many of which occur during hours of darkness, primarily because of insufficient visibility.

It was through a detailed analysis such as this that the writer arrived at the probable 75% reduction in accidents experienced to-day, through proper highway improvements. Neither Mr. Lavis nor Mr. Simpson offers any factual data to support their contentions.

Further indication of the favorable effect of roadway design on present-day accidents may be shown from a comparative study of the accident rate on a million-vehicle-mile basis along a section of an important highway in New Jersey that contains most of the advanced features herein concerned (with the exception of a center island dividing opposing flows of traffic) with sections of a surface roadway not embodying any of these characteristics.

The accident experience for a period of one year along State Highway Route No. 25 (U. S. Route No. 1, including the 12th Street viaduct, the depressed highway and the Pulaski Skyway" which represents the main approach to the Holland Tunnel, equaled 5.71 accidents per million vehicle miles, whereas for three sections of a surface route—State Highway Route No. 26 (U. S. Route No. 1) in South Brunswick, Plainsboro, and West Windsor Townships—the accident experience during the same year equaled 10.12, 10.88, and 10.34, respectively. A center island along the viaduct, the depressed roadway and the Skyway, would produce further reductions in accident experience.

Another indication of the benefits derived from a controlled highway is the accident experience along the Merritt Parkway in Connecticut, opened to vehicular traffic in June, 1938. Accident experience for the first few months of operation indicates a rate of 0.13 accidents per million vehicle miles of travel as compared with an average rate of 3.1 for the entire highway system of New Jersey.

Both Mr. Lavis and Mr. Simpson are of the opinion that, with all hazards removed from the roadways, motorists will be (as Mr. Simpson states), "lulled into an entirely false sense of security," and that the average speed of the vehicles will increase materially.

Speed surveys made along sections of improved highways, in New Jersey, such as four-lane divided roadways, do not support this contention. It is true that these roadways do not contain all the features of a controlled highway but intersection frequency is such that there is little, if any, border interference. The average speeds of vehicles over these roadways are not substantially different from the speeds along other roadways of the State, other conditions being equal.

In support of his contention, Colonel Kelly cites the experience in the Holland Tunnel as an example of effective enforcement. Since its opening, the Holland Tunnel has had an admirable accident record—a record for which the tunnel authorities can justly be proud. However, in the humble opinion of the writer, this record is due not alone to extraordinary enforcement activities plus the "no passing" regulation but, also, in no small measure, to the elimination of usual conflicts normally experienced or possible along ordinary present-day highways. In other words, the Holland Tunnel is, in a practical sense, a controlled highway—a highway designed for safety.

Colonel Kelly also states that since the passage of an ordinance prohibiting commercial vehicles from using the Pulaski Skyway, and since an increase in enforcement activities along the Pulaski Skyway, fatalities have ceased. The accident records along the Skyway for the five years, 1934 to 1938, inclusive, do not bear out this statement. As a matter of fact, in this 5-yr period, twelve persons were killed as a result of motor-vehicle accidents within the boundary lines of Jersey City and Kearny.

The history of industrial safety is somewhat parallel to the present highway accident situation. When industrial accidents became sufficiently extensive to warrant attention, industrialists first attempted prevention through a program based entirely on worker-safe practices and completely ignored machine safeguards.

The meager results soon determined that the cart was before the horse, and it was not until proper and adequate safeguards were applied that industrial accidents declined appreciably. In 1938 industrial accidents were less than half of the number twenty-five years ago.

As stated previously, the solution of the motor-vehicle accident problem is dependent upon the application of proper and adequate highway safeguards plus the use of safe practices on the part of highway users. Admittedly, the reconstruction of streets and highways in the manner herein discussed (that is, the rebuilding of highways to eliminate all possible conflicting or interfering flows of traffic by physical separation or segregation) would be economically impossible. However, if the public is to avoid the catastrophes occurring daily along roadways of the United States, it is essential that roadways of the future include design features which automatically lessen the importance of human failures.

RELATIVE FLEXURE FACTORS FOR ANALYZING CONTINUOUS STRUCTURES

By Ralph W. Stewart,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Frederick Shapiro, Dean F. Peterson, Jr., George W. Housner, Homer M. Hadley, Adolphus Mitchell, John B. Wilbur, Leon Blog, Å. Floris, D. B. Hall, Ralph W. Hutchinson, Arthur B. McGee, E. Neil W. Lane, and Ralph W. Stewart.

Synopsis

An effective method of analyzing the moments in continuous structures, by using the geometrical properties of elastic curves, is offered in this paper.

The area of any $\frac{M}{E\,I}$-diagram for a beam or part of a beam represents the curvature of the beam or the part to which the $\frac{M}{E\,I}$-area is related. This curvature is measured by the angle between the tangents to the elastic curve at the ends of the beam or of the part considered. It may be treated as a rotation of the tangent at one end of the curve with reference to the tangent at the other end, the center of rotation being the point where the center of gravity of the $\frac{M}{E\,I}$-area is projected upon one of these tangents to the elastic curve. In using the method, a graph consisting of a series of lines connecting these centers of rotation is substituted for a graph consisting of a series of moment diagrams. Each angle between the lines represents a moment area, both as to its magnitude and also as to the location of its center of gravity. It is not necessary that the graph be drawn to scale as the work is analytical. The method also involves use of the familiar mechanical requirements that the moments about a joint must balance, for equilibrium, and that the shear in a member must equal its combined end moments divided by its length. The series of lines referred to is designated as a "traverse of the elastic curves," because the lines which pass through points of support or joints in the structure will be, in fact, tangents to the curves formed by the flexed structure.

Note.—Published in January, 1938, *Proceedings*.

[1] Engr. of Bridge and Structural Design, City of Los Angeles, Los Angeles, Calif.

Although the method of analysis used in the paper is new, the construction of the type of graph used was described by the writer in a paper published in 1934.[2]

TRUE TRAVERSE AND EQUIVALENT TRAVERSE OF A SERIES OF ELASTIC CURVE UNITS

Fig. 1(*a*) represents a column with one end deflected laterally; Fig. 1(*b*) and Fig. 1(*c*) represent the induced bending moments and the true traverse of the elastic curves; and, Fig. 1(*d*) and Fig. 1(*e*) represent equivalent moment diagrams and an equivalent traverse. The moment diagrams (Fig. 1(*d*)) are considered as running the full length of the member, thereby fixing their centers of gravity at known fractions of the lengths. If the member is of uniform section, these points will be at the third points. If intermediate loading is applied, the simple moment diagram due to the loading, and its corresponding angle in the traverse, are added, as in Fig. 1(*f*) and Fig. 1(*g*). This assembly of moment diagrams is the same as that used in treatises on slope deflection and other forms of analysis.[3] The traverse diagrams express the same data as the moment area constants, but in a much more workable form.

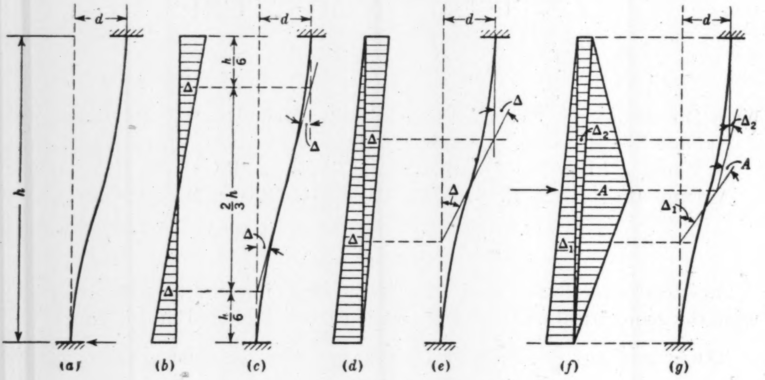

FIG. 1

In the following solutions, the symbol, Δ, represents the relative curvature in the entire length of a member due to an end moment, the different Δ-angles being identified by numerical subscripts. The symbol, θ, represents the relative angular rotation of a joint, the location being identified by a subscript. Symbols for fixed-end moments will follow the practice standardized for slope deflection.[3] Simple moment areas or their corresponding traverse angles will not be used, as solutions will be based on the fixed-end moments produced by any loading.

The stiffness of a member, as used in this paper, is measured by the moment, applied to one end of the member, necessary to produce a unit Δ-angle when the other end is hinged; or, briefly, is the ratio of an end moment to its Δ-angle. Under this definition, stiffnesses of a group of non-tapering members will have the same relative values as the stiffnesses used in the end-moment distribution method.[4] For tapering members, however, the relative stiffnesses will be different from those used in the end-moment distribution method, and will be easier to compute.

[2] "Analysis of Continuous Structures by Traversing the Elastic Curves," by Ralph W. Stewart, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 105.

[3] *Bulletin 108*, Eng. Experiment Station, Univ. of Illinois; also "Moments in Restrained and Continuous Beams," by F. E. Richart, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 51.

The values of the separate items of curvature in the members, which are the angles in the traverse of the elastic curves, constitute the flexure factors mentioned in the title.

APPLICATION TO A CONTINUOUS BEAM OF NON-TAPERING SPANS

In Fig. 2 it is desired to determine influence lines for a load moving along Span *B C*. The relative stiffnesses of the spans are indicated by the numerals in circles.

Apply a moment at Joint *B* as shown in Fig. 2(*b*). The next step is to draw the traverse for the entire structure. This is easily done by the following procedure: (1) Draw Line 31-51 representing the rotated position of the tangent to the elastic curve at Joint *B*; (2) from Point 51 (which is under the third point of the span) draw Line 51-9 which, if produced, would pass over Joint *C*, and under the third point from the right end of Span *B C* (directing Line 51-9 to pass over Joint *C* is done because there is restraint at Joint *C*, and passing it under the third point mentioned indicates that the restraint is less than fixture); (3) from Point 9 draw Line 9-18 representing the tangent to the elastic curve passing through Joint *C*, and continue the traverse to Point 6, all angles being opposite the third points of the beam; and (4), since the hinged joint at End *E* offers no restraint, the traverse is finished by drawing a straight line from Point 6 to Point 2.

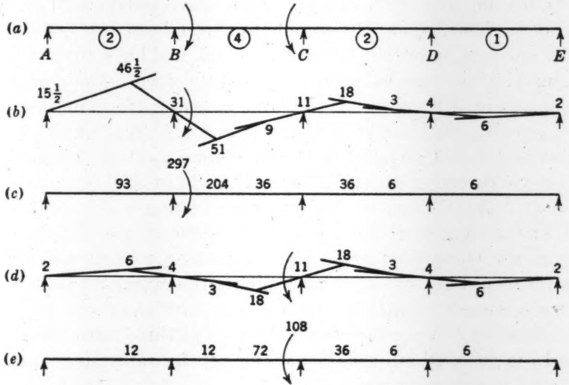

FIG. 2

Now, assign the arbitrary values of 2, 6, and 4, to the angles of the triangle in the traverse of the right span, these values being proportional to the opposite sides of the triangle. Since $M_{DC} = M_{DE}$ and since Span *C D* is twice as stiff as

---

[4] "Analysis of Continuous Frames by Distributing Fixed-End Moments," by Hardy Cross, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1.

Span $D\ E$, the angle due to M_{DC} will be one-half the angle due to M_{DE} giving it the value, 3, as shown. (The reason for assigning the even number, 2, to the rotation at End E was to avoid fractional values in Span $C\ D$, this division by 2 being foreseen). The next Δ-angle to the left of 3 is quickly obtained by the following deflection computation: Using one-third the length of the span as the unit of length, $(4 \times 3) + (3 \times 2) - \Delta \times 1 = 0$. Therefore, $\Delta = 18$. The rotation of Joint C is $4 + 3 - 18 = -11$. Again, by stiffness ratios, the angle at the left of Joint C is 9 and, proceeding as described, the rotation at Joint B is found to be 31. The two remaining angles in Span $A\ B$, being proportional to the opposite sides, are, respectively, 1.5 and 0.5 of 31, or 46.5 and 15.5.

Fig. 2(*b*) now shows all relative flexure factors for the beam due to a moment at Joint B. To reduce the relative flexure factors to relative moment factors, multiply them by the stiffness factors of their respective members. All the moments thus obtained resist the clockwise rotation of Joint B. The applied moment that produces these resisting moments is the numerical sum of the resisting moments acting at Joint B, and is equal to 297, as shown in Fig. 2(*c*). Note that if this moment, 297, acts through Member $B\ C$ as a medium, the actual moment, M_{BC}, will be the applied moment, 297, less the resisting moment, 204, leaving an actual moment of 93, which balances $M_{BA} = 93$. For any fixed-end moment, M_{BC}, the moments throughout the beam can now be computed by one setting of the slide-rule, as each will have the same ratio to its corresponding relative moment in Fig. 2(*c*) that the fixed-end moment has to 297.

Fig. 2(*d*) and Fig. 2(*e*) represent the same procedure for a moment at Joint C. In this case, another traverse beginning with an arbitrary angle assumption at End A, is run to Joint C. Owing to the accidental sequence of stiffness factors, each traverse yields the same end slope, 11, at Joint C. Ordinarily, the computed slope at Joint C, due to the traverse starting with an arbitrary angle assumption at the right end would not be the same as the computed slope at C resulting from the traverse starting with an arbitrary angle assumption at the left end; and it would be necessary to eliminate the difference in slopes at C with one slide-rule setting by multiplying all flexure factors on one side of the joint by the ratio necessary to equalize the end slopes at this joint. With the data in Fig. 2(*c*) and Fig. 2(*e*), all joint moments can now be determined quickly for any set of fixed-end moments in Span $B\ C$.

This beam was selected because it has heretofore been used as a demonstration problem and this solution may be compared with slope deflection solutions heretofore published.[5] The superiority of the solution by flexure factors will become greater if more spans are added. The extension of the traverse computation across another span is a small item, whereas, with slope deflection, and also with methods based on virtual work, another simultaneous equation is added to an already cumbersome group.

For a complete solution of this structure, for influence lines involving any fixed-end moments in any span, it is only necessary to run one traverse computation in each direction the entire length of the beam and then obtain all other values by simple ratios requiring only a single setting of the slide-rule for any series of moments. These right and left traverse computations have an automatic check by Maxwell's theorem of reciprocal deflections since the final moment at Joint D for an angle assumption at End B will be the same as the final moment at End B due to the same angle assumption at End D. As far as the writer knows, this elegant check, which avoids duplication of computations, is not available in automatic form with any other method.

For influence-line computations, involving side-sway of an unsymmetrical frame, as illustrated by Fig. 3, it is necessary to determine a set of relative flexure factors for each moving joint and the unbalanced shear resulting from them. The remainder of the work is by direct proportion and summation.

FIG. 3

To illustrate: Fig. 3(a) shows a set of flexure factors, computed easily by mental arithmetic, beginning with the relative value of 1 for the lower angle in the right column and progressing around the frame in the direction, $D\ C\ B\ A$. The numerals in parentheses opposite the column flexure factors are the corresponding moment factors computed on the basis of accepting the beam as representing the standard of stiffness, so that its flexure factors and moment factors are equal. The column moment factors are then equal to their flexure factors multiplied by the ratio of column stiffness to beam stiffness. Adding the moment factors for M_{BA} and M_{BC} it is found that the fixed-end moment acting on Joint B to produce these relative moment factors is 9. If this fixed-end moment acts through the beam as a medium, the actual moment in the beam is equal to the fixed-end moment, 9, minus the resisting moment, $5 = 4$, which balances the moment, 4, at the top of the column. The upper numbers of each group beside the columns in Fig. 3(*d*) (namely, 222, 444, 111, and 56) are the moments without side-sway for a fixed-end moment of 1 000, being $\frac{1\,000}{9}$ times the moment factors in Fig. 3(*a*).

For side-sway correction the unbalanced shear due to these moments is computed assuming the height of the frame as equal to 1. This unbalanced shear of 500 is illustrated by the arrow at Joint *B*, in Fig. 3(*b*), and the structure must deflect to the right until resisting moments sufficient in magnitude to hold the structure in equilibrium are developed. To obtain these moments, first consider the frame deflected as illustrated by Fig. 3(*b*), without rotation at Joints *B* or *C*, causing moments of as yet unknown, and of unassumed, magnitude but with directions illustrated by the curved arrows. In order to transform this into a true picture of flexure by releasing Joints *B* and *C* so they can rotate, it is necessary to obtain a series of flexure and moment factors for Joint *C*, as illustrated by Fig. 3(*c*). This is done by the same procedure as for Fig. 3(*a*), beginning with the angles in the left column. These assumed column flexure factors were selected so that in crossing Joint *C* from the column to the beam, the multiplication by the stiffness ratio of $\frac{2}{3}$ would give a whole number. It is found by easy mental arithmetic that the flexure and moment factors shown in Fig. 3(*c*), are produced by a fixed-end moment of 27.

The flexure of Fig. 3(*b*), may now be evaluated. The method usually given in existing treatises is to distribute the unbalanced shear between the columns in proportion to their $\frac{I}{l^3}$-values, or to distribute the moments due to the shear in proportion to $\frac{I}{l^2}$-values. The writer considers this method somewhat undesirable because it requires remembering formulas and also because it is not a universal method applicable to tapering members. The following procedure is more easily remembered, equally easy to use, and is applicable to all types of members. Note that the equal deflections at Joints *B* and *C* in Fig. 3(*b*), are governed entirely by the inclined courses in the traverse along the centers of the columns. This will also be true if tapering members are used. For the case in hand, since each column has a constant value of *I*, the Δ-angles will be at the third points, and since the columns are of equal length all Δ-angles will be equal and the distribution of moments will be in proportion to the stiffness factors. For the general case, the distribution of moments is obtained by taking relative Δ-values directly from the geometry of the figure and reducing them to relative moment values by multiplying them by the respective stiffness factors. For the case in hand the most convenient set of relative moment values is obtained by adopting the trial moment of 27 in Fig. 3(*c*), as the relative end moment for Column *C D* in Fig. 3(*b*). For M_{BA} and M_{AB} in Fig. 3(*b*), then, $\frac{4}{3} \times 27 = 36$, which is four times the trial moment in Fig. 3(*a*). Joints *B* and *C* are now held in their deflected position, but are made free to rotate. They will then turn until the moment at the top of each column is in balance with its adjoining beam moment and in accomplishing this adjustment the flexure at the bottoms of the columns will also receive an adjustment. The adjustments of the column moments due to the rotation of Joint A are obtained by multiplying the moments in Fig. 3(a), by $\frac{36}{9} = 4$, and are written on Fig. 3(b). The moments due to the adjustment of Joint C are copied directly from Fig. 3(c).

It may be noted that the adjustment of moments at the bottoms of the columns is one-half that at the tops of the columns, corresponding to a carry-over factor of one-half. However, this factor of one-half is for the special case of non-tapering members and the method of this paper does not use or advocate carry-over factors.

By summation, the final relative moments for side-sway influence are 30, 24, 21, and 24, corresponding to a side-sway force, or the shear of their sum = 99. The side-sway moments due to any shear can now be determined by direct proportion.

For a fixed-end moment, $M_{BC} = 1\,000$, the column moments without side-sway are $\frac{1\,000}{9}$ times the column moments in Fig. 3(a), giving a computed shear of 500. The correction moments for side-sway will be $\frac{500}{99}$ times the moments in Fig. 3(b). The column moments without side-sway, the side-sway correction moments, and the final column moments, are shown on Fig. 3(d).

FIG. 4

Multi-Span Rigid Frame with Variable Moment of Inertia.—Fig. 4(a) represents a five-span rigid-frame bridge, the deck spans having parabolic soffits. The moment-area constants for each member may be obtained by the method described by George E. Large, Assoc. M. Am. Soc. C. E.,[6] or by tables based on integrations. In this structure all crowns are 27 in. deep, the haunches over the centers of piers are 54 in. deep, the piers are 40 in. thick, and d^3 is assumed to represent relative I-values. Young's modulus, E, being constant throughout, is omitted from the computations.

---

[6] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 104, Fig. 48.

It is desired to obtain influence lines for any loading. Rotate Joint H as shown in Fig. 4(c) and draw the traverse diagram. Designate the relative values of the angles in Column $B\ C$ as 1, 2, and 1, as shown. For Span $A\ B$, the angles in the traverse triangle, being proportional to the opposite sides are computed, from the assumed relative joint rotation of 1, to be 0.69 and 1.69. The Δ-angle of 1.69 corresponds to a moment of 1.31 and the Δ-angle of 2 for the column corresponds to a moment of 3.33, these values being entered in their respective places on the traverse diagram.

These two moments, which act contra-clockwise, must be balanced by a clockwise moment, M_{BD}, equal to their sum, or 4.65. Enter this in Fig. 4(c) and compute and enter its corresponding Δ-angle of 7.11. The regular form of traverse equation from Joint B to Joint D now gives $1 + 7.11 \times 0.59 - 0.41\,\Delta = 0$, from which Δ for $M_{DB} = 12.65$ and its moment $= 8.28$ as shown. Enter these in Fig. 4(c) and by summation of angles obtain $\theta_D = 4.55$. The traverse angles for Column $D\ E$ are now added to the figure, the top moment in the column $= 15.13$ computed, entered on the figure and combined with the 8.28 deck moment to get $M_{DF} = 23.41$. This process is then repeated across the structure, and it is found that M_{HF} must equal 711.5 to produce the relative flexure factors and relative moments shown in Fig. 4(c). Since the structure is symmetrical the same relative factors may be reversed to compute the effect of a moment at Joint B. If the structure were not symmetrical a right to left traverse would be computed beginning with an angle of 1 to Joint H and ending, if correctly computed, with an external moment of 711.5 at Joint B. The distribution factors for fixed-end moments at Joints D and F are computed as already explained for Fig. 2. The effect of any fixed-end moment is now computed by simple ratios, and the effect of any combination of fixed-end moments can easily be tabulated.

Application to Closed Box-Frame.—In a closed box-frame each flexure factor is governed by stress flow along two separate routes. The solution is illustrated by Fig. 5, which shows such a structure, subjected to unsymmetrical loading consisting of a single fixed-end moment at Joint B. Designate the rotation at Joint D by χ and traverse from Joint D to Joint B by Routes $D\ C\ B$ and $D\ A\ B$. The first traverse gives $\theta_B = 5.5\,\chi + 3$, and the second traverse gives $\theta_B = 7\,\chi - 4$. Equating these two values of θ: $\chi = 4.667$; from which value all flexure factors may be evaluated and the moments determined. The solution can then be extended to include side-sway corrections by the procedure applied to Fig. 3.

Application to Partial Fixture.—An easily understood and easily used method for treating partial fixation is available. In Fig. 6, let it be desired to analyze the effect of a partly fixed-column base. Add to the figure an imaginary underground member, as shown in dotted lines. Any desired degree of fixation can now be taken into account in the design by a proper adjustment of the stiffness factor, K_0, of the imaginary member, with reference to the stiffness factor, K, of the column. For 50% fixture, $K_0 = K$. For any ratio of fixation, designated as r, $r = \dfrac{K_0}{K_0 + K}$; and, $\theta = \dfrac{1 - r}{2r} \Delta_1$. For 50% fixture $\theta = \frac{1}{2}\Delta$.

Application to Large Buildings.—Buildings like the Empire State Building, in New York City, and even those of much lesser size, have so many members

that it is impracticable to analyze them by extending moment distribution over their entire width and height. This is especially the case when slow convergence of the successive approximations is encountered. For such cases a plausible method is to assume a degree of partial fixation at the various bound-

ary joints around the part that is to be analyzed. For example, in Fig. 7, the moments in Girder *G H* can be determined accurately with only ordinary judgment as to the degrees of fixation at Joints *A*, *B*, *C*, *D*, *E*, and *F*. This is because a given percentage of error in assuming the moment at Joints *A*, *B*, *C*, *D*, *E*, or *F* will produce a smaller percentage of error in M_{GH} or M_{HG}.

SUMMARY AND CONCLUSIONS

It has been noted that the essential feature of the method set forth herein is to establish, as centers of rotation, the points of intersection of the tangents to elastic curves. Slope deflection is based on rotations at the joints where, due to continuity, the governing tangents to elastic curves do not establish angles. No simultaneous equations were used in this paper, whereas with slope deflection and also with the Maxwell-Mohr method of virtual work, very annoying groups of simultaneous equations would be needed to solve some of the problems presented.

A distinction between the method of relative flexure factors and end-moment distribution (which also avoids simultaneous equations) is that the latter begins the computation at the member affected by the load and works outward toward unloaded members, whereas the former begins the computation at a point remote from the loaded member and works toward it. The relative flexure-factor method does in a "once-over" computation what end-moment distribution accomplishes by a series of computations.

The writer feels quite confident that, for the class of structures illustrated in this paper, the method of treatment set forth will prove to be superior, not only in reduced arithmetical work but also in other respects, to the other methods mentioned.

DISCUSSION

FREDERICK SHAPIRO,[7] JUN. AM. SOC. C. E. (by letter).—In the conclusion to his excellent paper, Mr. Stewart seems too enthusiastic over the advantages of his method over that of end-moment distribution.

The writer, who has made an extensive study of the various methods of rigid-frame analysis, feels that for every problem there is at least one system of solution which is superior to others for speed in computation, or for accuracy, or for both. For example, in problems in which an approximate answer is desired quickly for a given loading, the Hardy Cross method[4] is excellent; for a short series of continuous beams, the theorem of three moments is superb, especially when modified by certain short-cuts; and for a rigid-frame bridge with curved beam, the method[8] used by A. G. Hayden, M. Am. Soc. C. E., is very convenient. For the problem of the multi-span rigid-frame bridge with variable moment of inertia which is solved in the paper, the method of transmission coefficients introduced by R. G. Brumfield,[9] M. Am. Soc. C. E., is probably a better one. For those who prefer graphical methods, conjugate points[10] offer an excellent solution to the continuous beam problems. The Beggs' deformeter[11] is ideal for a mechanical solution.

An objection might be raised to some of these methods because they involve the use of formulas. Formulas are intended as short-cuts; they express in one brief mathematical sentence what might occupy several paragraphs of written thought. The devices generally used to avoid them may be likened to going around the block to reach next door. It might be claimed that some of these methods do not give a picture of what is happening to the structure as computation progresses. Is it not easy and simple to put a coin in a slot-machine, pull a lever, and take what is desired from the proper compartment? There is a great advantage in applying this slot-machine principle to the solution of rigid frames in that mistakes are limited to arithmetical ones. The method of transmission coefficients,[12] in the writer's opinion, is one of the best for general application; not only does it give a good picture of the structure at all times, if the computer will pause to look, but it also "grinds" out the solution, if the computer cannot take time to stop.

If only one system of analysis is to be used, it is a matter of personal opinion what method should be selected; but actually different methods handle certain problems more advantageously than others, depending on the purpose in view.

DEAN F. PETERSON, JR.,[13] JUN. AM. SOC. C. E. (by letter).—The extension of the moment area principle, by the use of flexure factors, seems to the writer to have widespread application to continuous structures. The criterion for its application, as with the other so-called "special methods," is: (1) That the members have essentially straight center axes; and (2) that the deformations are essentially flexural.

[13] Troy, New York.

Although actual influence lines for moment or shear at any section are not generally necessary to analysis, when cases occur in which they are desirable, they may be constructed directly from the method of flexure factors and the use of the Müller-Breslau relation between influence lines and deflection curves.[14] For a moment at Point B (see Fig. 8(*b*)), a unit rotation of the axes is inserted and the flexure factors are written. Span $A\,B$ is solved since $M_{BA} = M_{BC}$. The unit rotation is represented by the number, $31 + 68 = 99$. The actual end rotations of the various members may be found by dividing through by 99. The ordinate of the influence line may be found graphically, with the aid of the funicular polygon, or analytically, by a convenient, self-checking table. It is only necessary to construct the deflection curve of each member separately. To do this the length of the member may be divided into a finite number of elementary lengths, Δl. Then, the rotation in the length, Δl, is $\frac{M\,\Delta l}{E\,I}$. This rotation, with sufficient accuracy, may be applied at the center of the length, Δl. Then the designer, knowing the end slopes of each member, traverses these rotations to form the deflection curve. Any accuracy desired may be attained by choosing a sufficiently small value of Δl. If one radian is taken as the initial rotation, the scale of the influence ordinate, in foot-pounds, will be the same as the scale of the abscissa, in feet. If, to begin with, some other rotation is used at the section, the scale of the ordinate will be equal to the initial rotation, in radians. In the graphical method the rotations, $\frac{M\,\Delta l}{E\,I}$, are plotted as vertical forces, $A\,B$, $B\,C$, etc., on the equivalent force diagram. It is not necessary that the true value of $\frac{M\,\Delta l}{E\,I}$, or that the actual moments for the known end slopes, be computed, because the rotations, $A\,B$, $B\,C$, etc., may be plotted on the equivalent force diagram to any scale desired in any one span and, therefore, need only be relative. All that is required is that the rays on the equivalent force polygon, through the points, A and G, be parallel to the end tangents of the beam (see Fig. 8(*d*)).

The influence line for moment at the center of Span $B\,C$ may be drawn (see Fig. 8(*e*)) almost as readily. The flexure factors are written from each direction up to 4.5 on the right and $3a$ on the left, in which a is a proportionality factor to balance the rotations from each direction. This factor may be evaluated since $\Delta_1 = \Delta_2$ (because the moments producing them are equal) and $3 \times 8a + 2 \times 3a + \Delta_1 = 3 \times 11 + 4.5 \times 2 + \Delta_2$ (since the deflection is the same, approaching from the right or from the left). Thus a is found to be $\frac{7}{5}$ and it is possible to express the rotations on each side as comparative units; Δ_1 and Δ_2 may be found from statical considerations of Beam $B\,C$ because, disregarding

FIG. 8

the common elastic factor necessary to change the rotations into end moments, the end shear, V, equals $\frac{M_{CB} - M_{BC}}{l} = \frac{4.5 - 4.2}{l} = \frac{0.3}{l}$, and the moment at the center is $M = 4.2 + \frac{0.3}{l} \times \frac{l}{2} = 4.35$ which is the rotation, Δ_1. To reduce to exact rotations, the flexure factors are divided by $11.2 + 4.2 + 4.35 + 4.35 + 4.5 + 11 = 39.6$. It is to be noted that, for rotations in Span $B\,C$, the stiffness is doubled since the member is cut in the center. The use of the funicular polygon, although not shown in Fig. 8, may be extended to this case and to the case for a shear influence line.

For shear at Point $B\,C$ (Fig. 8(*f*)), deflect Span $B\,C$ from Span $B\,A$ without rotation and write the flexure factors. They are determined in Span $A\,B$ since $M_{BA} = M_{BC}$. The unit deflection is represented by the quantity, $\frac{2}{3} l \times 11 + \frac{1}{3} l \times 9 = \frac{31}{3} l$. To reduce to exact scale, all the rotations must be divided by $\frac{31}{3} l$.

For a settlement, δ, of Support B (Fig. 8(*g*)) the problem is likewise easily solved. The flexure factors are written from the right end, and since $M_{BA} = M_{BC}$, $\Delta_1 = 2\Delta_2$. Equating the deflections and rotations at Point B calculated from the right side to those calculated from the left side, $\theta_1 - \frac{1}{3}\Delta_1 = 11 + \frac{2}{3} \times 9 - \frac{1}{3}\Delta_2$ and $-(\theta_1 - \Delta_1) = 11 + 9 - \Delta_2$. Solving these three equations simultaneously, $\Delta_2 = \frac{111}{8}$, $\theta_1 = \frac{173}{8}$, and $\Delta_1 = \frac{111}{4}$. Since δ is represented by $\frac{173}{8} l - \frac{1}{3} l \times \frac{222}{8} = \frac{99\,l}{8}$, the actual rotations are obtained by dividing by $\frac{99\,l}{8\,\delta}$. Although simultaneous equations were used in the last solution they were very simple and solvable almost by inspection.

The foregoing two problems presented are solved for a very simple case. The solution may be extended, without difficulty, to frames of greater complexity and to members with varying moment of inertia. In general, the directness of the attack made and the inevitable final check furnished by the method of flexure factors will undoubtedly cause it to be viewed with favor as a means of analyzing many problems in continuous structures. The writer does not know of a more direct method for the solution of the complete influence line for a continuous frame.

GEORGE W. HOUSNER,[15] JUN. AM. SOC. C. E. (by letter).—The method of presenting this paper can be criticized in that Mr. Stewart professes to derive his solution from the theory of moment-areas and from geometrical principles. Upon examination, however, it is seen that the method of traversing continuous structures is identical with the conjugate beam theory, except that the author chooses to represent the $\frac{M}{E\,I}$-areas graphically as angle changes.

---

[15] Pasadena, Calif.

Although the author sketches a traverse of the deflected structure he reasons from the conjugate beam theory. For example, under the heading "Application To a Continuous Beam of Non-Tapering Spans," he states "Now, assign arbitrary values of 2, 6, and 4, to the angles of the triangle in the traverse of the right span, these values being proportional to the opposite sides of the triangle." This statement is objectionable, because a triangle with sides proportional to 2, 6, and 4 is an impossibility. These proportions define a straight line and not a triangle. They are perfectly proper in any application of the conjugate beam theory as distinct from the principles of geometry.

To demonstrate that the method of traversing continuous structures is the same as the conjugate beam theory, the author's first example is reproduced in part. For any real beam, construct a fictitious beam of equal length loaded with the $\frac{M}{E\,I}$-diagram. Then the shear at any point on the fictitious beam is equal to the rotation at that point on the real beam, and the bending moment at any point on the fictitious beam is equal to the deflection at that point on the real beam. Therefore, given the continuous beam shown in Fig. 9(*a*), the approximate bending moment diagram can be sketched as shown in Fig. 9(*b*).

Assigning an arbitrary value of 2 to the reaction at End *E*, it follows from statics that the triangular load on the fictitious beam, *D E*, equals 6 and the left reaction of Beam *D E* equals 4. These beam reactions represent the rotation of the real beam at the supports. Therefore, the right reaction of Span *C D* is also 4 since there is continuity over the supports. Then, since M_{de} equals M_{dc} the value of the triangle load (measured by M_{dc}) is $6 \times 1 \div 2 = 3$. The deflection at Reaction *C* is zero, so that, taking moments about Point *C*, with the length of beam equal to 3, Area $\times\ 1 - 3 \times 2 - 4 \times 3 = 0$ and the area equals 18. From statics the reaction at Point *C* equals $18 - 3 - 4$ which is 11.

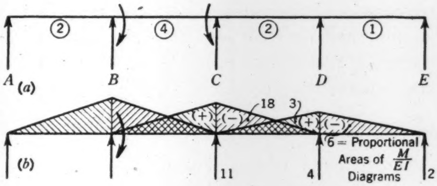

FIG. 9

This reasoning continued will reproduce the author's solution. The other examples in the paper can be solved similarly.

Although it may be simpler to sketch the traverse of a beam than to sketch the bending moment diagrams, the use of the traverse is less obvious. This is to be expected as it is a secondary form of the conjugate beam theory. In view of this it is doubtful whether the use of the traverse is justified as it somewhat obscures the reasoning, thus making the solution more difficult to comprehend.

Homer M. Hadley,[16] Assoc. M. Am. Soc. C. E. (by letter).—When the tangled complexity of the Gordian knot was laid before Alexander that he should untie it, he drew his sword and cut it. This was a wholly new approach to the problem but it effectively disposed of difficulties.

Mr. Stewart has devised a somewhat similar method of dealing with stress distribution in continuous structures, at least in all their common varieties. Essentially, it is recognition of the fact that the flexed form of a beam is a direct expression of the stresses that are in it. However, his method proceeds a step further in recognizing that the direction of the tangents to the elastic curve at the ends of a member and the direction of an intermediate course connecting critical points upon the end tangents tell all that needs to be known —the direction and magnitude of the end moments. Therefore, in lieu of much involved clutter there is presented a method of analysis which, by means of the most elementary geometry and a fundamental or two of mechanics, yields an exact solution by a single operation.

It is not the least important part of Mr. Stewart's method that its first step is to draw a traverse diagram, the shape of which reflects the deformations in the structure it represents. This diagram requires no scale, and it can be exaggerated and distorted so long as it shows, correctly, the inclination of its courses with respect to one another. It is a framework upon which the relative angular changes are calculated and recorded. It furnishes, at all times, a valuable image of the structure under consideration, its various inclined courses indicating clearly the deformations and stress tendencies in the original subject.

However, the essential feature of the method is its determination of the relative magnitude of the moments at the ends of a member by expressing these moments as functions of angles developed at certain critical points in a traverse and then developing the respective magnitudes of the angles from the geometrical necessities of the situation. It is because the flexural effects of a moment applied at one end of a member can be represented graphically by the proper intersection of two lines at a point offset from the center of gravity of the $\frac{M}{E\,I}$-diagram for this moment and member that this method has the elegant nicety which characterizes it.

Beginning at the member in the system most remote from the one subjected to applied stress, convenient relative values are assigned to the angles developed in it under the conditions of end restraint which prevail at its extremity. Thence, one proceeds to the next member and the relative values of the angles in its traverse are precisely determined from the relationship which that member's stiffness bears to the first member's stiffness; and so on, progressively obtaining angle values which are accurate and exact in their relationship to one another. Either a final or concomitant conversion of these angles gives a set of end moments likewise accurately related to one another and to the applied moment that produces them. With this series of moments established, multiplying it by the ratio which any other applied or causal moment bears to the applied moment of the established series gives correct values for the new series. It is simplicity itself.

---

[16] Regional Structural Engr., Portland Cement Assoc., Seattle, Wash.

The writer believes that Mr. Stewart could have improved his paper if, at the outset of his illustrative problems, he had stated in definite categorical detail the procedure to be followed: Do this—then do this—then do this, etc. After all, it is in the use and application of a method that its value resides. The reasons for the various steps can be elaborated in the discussion of the several examples.

Fig. 4(*b*) would be improved if "stiffnesses" were substituted for "Relative Δ" in each case. When every one is familiar with stiffnesses, why introduce another term for another aspect of the same thing?

ADOLPHUS MITCHELL,[17] JUN. AM. SOC. C. E. (by letter).—The writer has used the traverse method since its first presentation.[18] The ensuing years have given the opportunity to test the method in the design office and classroom. It is an attribute that engineers familiar with the area-moment method experience no difficulty in analyzing continuous structures by traversing the elastic curves. The present paper does much to simplify further the traverse method and is a distinct contribution to engineering literature.

The subject of closed box-frames has scarcely been touched. The true shape of the traverse is seldom known to the designer at the beginning of an analysis. This point is illustrated by Figs. 10 and 11 showing two variations of Fig. 5. The problem becomes more difficult in multiple box-frame design especially in extending existing culverts many of which utilized 12-in. interior walls. The writer would like to see a general solution of this difficulty that would require little added work for the designer.

Many problems show great advantages in the traverse solution. The following problem was solved by the slope-deflection method by Mr. A. W. Fischer, in 1936.[19] Fig. 12 shows the required dimensions and values of K, and Fig. 13 shows the traverse. To determine D_v, Fig. 14 will be used. Applying trigonometry,

$$\delta_1 = h - h_s \cos(\theta + \alpha) = h - h_s (\cos\theta \cos\alpha - \sin\theta \sin\alpha) \dots\dots (1)$$

Since α is very small, $\sin\alpha = \alpha$; $\cos\alpha = 1$; $h_s \cos\theta = h$; $h_s \sin\theta = l$, and $\alpha = \frac{D}{h_s}$. Hence,

$$\delta_1 = h - h + l\alpha = l\alpha = \frac{lD}{h_s} \dots\dots\dots\dots\dots\dots (2)$$

Likewise,

$$\begin{aligned} \delta_2 &= h_s \cos(\theta - \alpha) - h = h_s (\cos\theta \cos\alpha + \sin\theta \sin\alpha) - h \\ &= h + l\alpha - h = \frac{lD}{h_s} \dots\dots\dots\dots\dots\dots (3) \end{aligned}$$

and,

$$D_v = \delta_1 + \delta_2 = 2\frac{lD}{h_s} = 0.329\,D \dots\dots\dots\dots\dots\dots (4)$$

FIG. 15

Keeping in mind that breaks in the traverse occur at the third points of members of constant moment of inertia and using the traverse of the beam, the offsets at End *B*, Fig. 11, may be added to obtain,

$$0.329\,D + \left(\Delta - \frac{11\,280}{340.3}\right)9.53 - \frac{2}{3}\,(9.53) + \frac{1}{3}\,(9.53) = 0 \ldots\ldots (5a)$$

Similarly, for the column,

$$\frac{2}{3}\,(31.59)\,\Delta - \frac{1}{3}\,(31.59)\,\frac{11\,280}{340.3} - D = 0 \ldots\ldots\ldots\ldots\ldots (5b)$$

Solving Equations (5) simultaneously, $\Delta = 26.3$; and:

$$M_{AB} = 2\,K_1\left(\text{area of }\frac{M}{I}\text{-diagram}\right) = 2(11\,280)\,1 = 22\,560\text{ ft-lb};$$

$$M_{AD} = 2\,K_2\left(\text{area of }\frac{M}{I}\text{-diagram}\right) = 2(304.3)\,\frac{11\,280}{340.3} = 22\,560\text{ ft-lb};$$

and,

$$M_{DA} = 2\,K_2\left(\text{area of }\frac{M}{I}\text{-diagram}\right) = 2(340.3)(26.3) = 17\,930\text{ ft-lb}.$$

These values are based on an assumed area of the $\frac{M_{AB}}{I}$-diagram equal to unity. The corresponding value of P is obtained by taking moments as shown in Fig. 15, giving $P = 2\,H = 4\,180$ ft-lb.

The given value of P is 26 800 lb and the correct moments are obtained by direct proportion, resulting in $M_{AB} = 22\,560\left(\frac{26\,800}{4\,180}\right) = 144\,600$ ft-lb; $M_{AD} = 22\,560\left(\frac{26\,800}{4\,180}\right) = 144\,600$ ft-lb; and,

$$M_{DA} = 17\,930\left(\frac{26\,800}{4\,180}\right) = 115\,000\text{ ft-lb}.$$

All computations have been made with a slide-rule and the explanation assumes familiarity with the author's paper.

For continuous beams the three-moment theorem and moment distribution cannot compare with the author's method. This is especially true when members of variable cross-section are involved because of the directness of its application. Slopes and deflections at any point are easily found by using the load, shear, moment, slope, and deflection series of diagrams as repeatedly brought out in discussions of the shear-area method.[20] Simpson's rule may be used to advantage when great accuracy is desirable in handling areas bound by complex curves.

No method is best for handling all problems, but any designer would be well repaid for time spent in learning when to use the Stewart traverse method.

JOHN B. WILBUR,[21] ASSOC. M. AM. SOC. C. E. (by letter).—In presenting a new expedient for analyzing continuous structures, Mr. Stewart has contributed a paper of real interest. Just what arrangement of the details of a solution leads to the best results is a difficult matter to determine, but certainly Mr. Stewart's procedure for analyzing continuous structures has the merit of simplified computation under some circumstances.

In simplifying analysis procedure, there is always danger that the reasoning involved will become obscure. The writer is of the opinion that simplicity of thought is of at least equal importance with simplicity of procedure. With this in mind, it might be questioned as to whether the concept of flexure factors does not pay too great a price for the advantage it may gain.

---

[20] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 947.

[21] Associate Prof. of Civ. Eng., Mass. Inst. Tech., Cambridge, Mass.

Although the process of traversing the elastic curve by assuming the slopes at certain joints, and progressively computing slopes at adjacent joints, is excellent under some circumstances, the same results can be accomplished with precisely the same mathematical steps by working directly from the moment-area theorems. Treating the $\frac{M}{EI}$ -curve as an elastic load, it may be shown easily that the following theorem holds: If a section, A–B, of a member which is initially straight, has its slope changed due to bending only, the slope at one end of the section, referred to the chord, A–B, of the elastic curve, is equal to the reaction at that end of an imaginary beam, A–B, which is carrying a distributed elastic load of intensity, $\frac{M}{E\,I}$.

For the case of an end-supported beam, if the entire beam is considered as the Section A–B, this theorem leads directly to the computation of true slopes referred to the original position of the axis of the beam, inasmuch as this original position of the axis coincides with the chord, A–B.

In applying this theorem, the following sign convention may be observed: (*a*) Positive values of $\frac{M}{E\,I}$ correspond to a downward elastic load; (*b*) negative values of $\frac{M}{E\,I}$ correspond to an upward elastic load; (*c*) an elastic reaction that acts in a direction to cause positive shear in the adjacent section of the beam considered, corresponds to a positive or clockwise slope; and (*d*) an elastic reaction that acts in a direction to cause negative shear in the adjacent section of the beam considered, corresponds to negative or counter-clockwise slope.

To determine the slopes obtained by Mr. Stewart in Fig. 2(*b*), by means of this theorem, one may proceed as follows:

(1) Sketch the resultant moment curve for the case under consideration as shown in Fig. 16(*a*), and sub-divide this moment curve into its component parts as shown by dotted lines. Note that all moments may be assumed as positive.

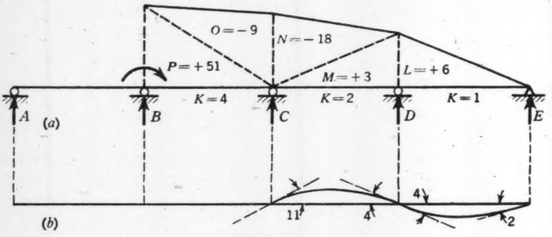

FIG. 16

(2) Assume that the slope at End E is -2. Note that this assumption corresponds to a counter-clockwise slope, as will actually occur at this point. It also corresponds to an upward reaction due to the $\frac{M}{E\,I}$ loading, since this produces negative shear to the left of End E.

(3) In order that the triangular elastic load shown by Area L may produce an upward reaction of 2 at End E, when acting on the end-supported beam, D-E, Area L must equal $+\ 6$; the elastic load, $\frac{M}{E\,I}$, must act downward, corresponding to positive moment.

(4) The elastic load, $L = +\ 6$, causes an upward reaction of 4 at Point D. This reaction causes positive shear to the right of Point D; and, the slope at this point, therefore, is equal to 4, and is clockwise.

(5) The moment area, L, is given by:

$$\frac{M_{DE}}{E\,I_{DE}} \times \frac{L_{DE}}{2} = \frac{1}{2\,E} \times \frac{M_{DE}}{K_{DE}} \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

Similarly, the moment area, M, is given by:

$$M = \frac{1}{2\,E} \times \frac{M_{DC}}{K_{DC}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

Since $M_{DE} = M_{DC}$, the following relation holds:

$$\frac{M}{L} = \frac{K_{DE}}{K_{DC}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

For the case under consideration, $\frac{K_{DE}}{K_{DC}} = \frac{1}{2}$, so that $M = \frac{1}{2}\,(+\ 6) = +\ 3$.

(6) Clockwise slope at Point D corresponds to positive elastic shear to the left of D in the beam, $C\,D$; hence, for purposes of considering the equilibrium of the elastic loads on Beam $C\,D$, the elastic reaction at Point D is downward, and equals 4. This reaction is due to the elastic loads, N and M, acting on Beam $C\,D$; whence, $N \times 1 + (M = +\ 3) \times 2 + 4 \times 3 = 0$; and $N = -\ 18$. This negative value shows that the elastic load, N, acts upward, corresponding to negative moment.

(7) The slope at Point C is now obtained by evaluating the elastic reaction at that point. The upward value of this reaction equals $\frac{1}{3}\,(3) - \frac{2}{3}\,(18) = -\ 11$; the reaction, therefore, is down; this causes negative shear to the right of Point C; and the slope at that point, therefore, is counter-clockwise.

In a similar manner, relative slopes may be determined at other joints. From the relative slopes, relative moments are easily determined.

Mr. Stewart refers to a solution for a continuous beam given by the writer[5] and suggests a comparison of the labor involved by the two methods. As explained in the closing discussion of the writer's paper, this example was included as a pedagogical step in leading the reader gradually into the more complicated problem of a building frame, rather than because it was believed to illustrate a desirable method of analyzing continuous beams.

Although the technique of Mr. Stewart's solution differs considerably from that suggested by the writer, the two methods have certain features in common.

Both are based fundamentally on the moment-area theorems, and both work, successively, from joint to joint.

LEON BLOG,[22] ASSOC. M. AM. SOC. C. E. (by letter).—Eight years have transpired since, in May, 1930, Hardy Cross, M. Am. Soc. C. E., published his valuable method of analysis.[23] As has been the case with the original analyses for continuous beams and for single span and continuous span arches, such publication has stimulated the presentation of improvements and of alternative methods of obtaining the same results as by the prototype. Of these additions to the subject, the one offered by T. Y. Lin, Jun. Am. Soc. C. E., in 1934,[24] was a variation of the Cross method. The writer has shown that the Lin method was applicable to one-story structures and offered quicker solutions than the Cross method when such structures had numerous spans. It was followed by one presented by the author[25] which was a combination of the area-moment method and a set of simultaneous equations for each member, based upon the concept that for every part of a bent beam a triangle may be conceived which has, for its three sides, the line joining the ends of the bent part and the two end tangents. The tangents form an angle which is equal to the sum of the two interior angles of the triangle and is measured by $\frac{M}{EI}$, which is Moment-Area Principle 1.[26] The series of tangents, when taken continuously along a beam or a structure, may be considered as a surveyor's traverse in conjunction with the attendant angles, a concept which gives Mr. Stewart's method its name.

The traverse method was followed by L. E. Grinter, Assoc. M. Am. Soc. C. E., in devising his method of balancing angle change,[27] and it, in turn, is now followed by a restatement of the Stewart traverse method which eliminates the cumbersome equations of the original presentation.

The purpose of this discussion is to register the advantages and disadvantages of each of these developments based upon the following criteria:

(1) Is the method a general tool, or is it a special tool of analysis?
(2) Must approximations be made as to the degree of end restraint in the terminal members in the highest story?
(3) Does the method yield approximate or accurate results?
(4) Is the method faster than its competitors?
(5) Is it easy to remember?

The Cross method is a general tool. It applies to all true continuous frames whether they are single or multi-storied. Distribution can be begun without approximations as to restraint in either the beams or the columns. This method yields approximate results which are accurate enough for the purpose. For certain problems it is not as fast as some of its competitors. It is the easiest method to remember.

[27] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 1020.

The direct method of moment distribution, by Mr. Lin, is not a general tool. It is not applicable to multi-storied structures without approximation as to end restraint in the terminal members in the highest story. The method yields approximate results which are as accurate as the Cross results. For one-story structures (such as bridges) for which influence lines are required, it is faster than the Cross method despite the extra preliminary computations required for the modified stiffness and carry-over factors which lead to its rapid convergence. Like the Stewart method it is a one-direction method. It is not as easy to remember as the Cross method.

The Grinter method of analyzing continuous frames by balancing angle changes is a general tool. It is not moment distribution in the strict sense of the term, although some of the moment distribution technique, such as balancing around a joint and carrying over angles instead of moments, is used. Approximations at the upper stories need not be made. The answers are approximate, but accurate enough for most purposes. It is distinctly not faster than its competitors and is the most difficult of all the methods proposed after the Cross method to remember. It is really slope deflection in reverse.

The restatement of the Stewart method is a special tool. It is not applicable to multi-storied structures inasmuch as assumptions as to restraint of the terminal members of the highest story must be made. For one-story, or closed, frames it is the most accurate of all the methods under discussion because it is distinctly not a method of approximation. This is because no convergence is involved in the solution of problems. As a special tool, it is faster than all the methods being discussed. This statement is made with the reservation that the user is not under the necessity of familiarizing himself with the method every time he has to use it. It is of use to those who are continually analyzing one-story and closed frames. It ranks second in ease of remembrance.

The Stewart method of analyzing continuous frames by flexure factors is neither a moment distribution, nor a slope deflection, method. For the end spans it makes use of Moment-Area Principle 1 and for interior spans it applies Moment-Area Principles 1 and 2. It involves less computation preliminary to obtaining the desired moment, but aside from that superiority it is not simpler than the Lin method.

Much is made by authors and discussers of the Grinter and Stewart methods of the point that the deflection of the structure can be visualized; but this is true of all the methods when used by competent engineers. Under dead load, live load, temperature, shrinkage, plastic flow, movement of the footings —laterally or vertically—or under earthquake movements, there is no difficulty in ascertaining the deflected shape of the structure. When, however, some, or all, of the distortion agents act simultaneously, the resultant shape is ascertainable only from the moment envelope, which may or may not be the result of the addition of moments of opposite signs. Under such load and natural phenomena combinations, the visualization advantage claimed for the Grinter and Stewart methods is not impressive and should not be a determinant in the selection of a method of analysis.

For those engineers who prefer not to tax their memories with new concepts of stiffness and the adaptation of long-known principles such as slope deflection and area moments in the alternatives to the Cross method, the latter, despite some additional calculation, will serve best for all continuous frames. For one-story frames, requiring influence lines, the modified Cross-Lin method is the fastest method of approximating moments by distribution; but review will be required before its use.

For closed frames and one-story structures, the Stewart method of traversing flexure factors will involve less computation. It will yield accurate results because it is not a method of approximation.

A. FLORIS, ESQ.[28] (by letter).—In the proposed method for analyzing continuous beams and rigid frames by means of the relative flexure factors, only the influence of the bending moments upon the deformation of the structure is taken into account. The influence of the shearing forces is neglected. This is the usual procedure in the analysis of continuous structures. However, cases may arise in practice, in which a knowledge of the influence of the shearing deformation is not only desirable but necessary. This is especially true in short bars of considerable depth.

In the following discussion the author's analysis will be modified in such a manner as to include the shearing deformation of structures composed of bars with constant section. This is done very easily, because all the necessary data for this purpose are already available.[29]

In developing his theory the author uses the distances of the centers of gravity of the moment areas from the ends of the bars, the stiffness factors of these bars, and the fixed-end moments. By considering the shearing deformation of the structure the distances of the centers of gravity from the ends of the bars (Fig. 17) are: $x_1 = 2\lambda$; and, $x_2 = 2\zeta$, in which,

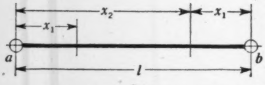

FIG. 17.—CENTROIDS OF JOINT MOMENT AREAS WITH SHEARS

$$\lambda = \frac{l}{6} - \nu \frac{\gamma}{l} \qquad (9a)$$

and,

$$\zeta = \frac{l}{3} + \nu \frac{\gamma}{l} \qquad (9b)$$

In Equations (9), $\gamma = \frac{I}{A}$; I = moment of inertia; A = sectional area; and $\nu = 3.0$ for steel and, approximately, 2.8 for concrete.

The stiffness factors in this case are for unyielding supports,

$$K = I \frac{\zeta}{\zeta^2 - \lambda^2} \qquad (10a)$$

and, for yielding supports,

$$K = \frac{I}{(\lambda - \zeta)\, l} \qquad (10b)$$

---

[28] Dipl.-Ing., Los Angeles, Calif.

[29] "Shearing Deformation in Continuous Beams and Rigid Frames," by A. Floris, *Journal*, Am. Concrete Inst., November–December 1937, p. 165.

In both cases the carry-over factor will be,

$$\beta = \frac{\lambda}{\zeta} \qquad (11)$$

By considering the shearing deformation of the structure, the fixed-end moments are expressed by,

$$S_{ab} = \frac{Q_r \zeta - Q_l \lambda}{(\zeta^2 - \lambda^2)\, l} \qquad (12a)$$

and,

$$S_{ba} = \frac{Q_l \zeta - Q_r \lambda}{(\zeta^2 - \lambda^2)\, l} \qquad (12b)$$

in which Q_l and Q_r are the static moments of the moment area of the freely supported bar relative to the left and right supports, respectively. For symmetrical loadings the fixed-end moments in Equations (12) reduce to the ordinary fixed-end moments, found in almost all handbooks on structural engineering.

For a concentrated load, P, at a distance, l_1, from the left and l_2, from the right supports, for instance, these moments are,

$$Q_l = \frac{P\, l_1}{6} (l^2 - l_1^2) \qquad (13a)$$

and,

$$Q_r = \frac{P\, l_2}{6} (l^2 - l_2^2) \qquad (13b)$$

If several concentrated loads, unsymmetrically spaced, are acting on the bar, the statical moments are found by substituting the values in Equations (13). It should be noted in passing that, if the structure is composed of different materials, the stiffness factors should be multiplied by the modulus of elasticity of the material, everything else remaining the same.

In all the foregoing expressions, λ and ζ are taken from Equations (9). By neglecting the last terms of this equation containing ν and γ and showing the influence of the shearing deformation, the expressions used by the author are obtained immediately.

The further analysis of the structure follows the steps that were so ably outlined by Mr. Stewart. For this reason a repetition of this procedure is not necessary.

In conclusion, it should be emphasized that the proposed method, in addition to its theoretical interest, has an intrinsic practical value. Dispensing with the inconvenient simultaneous equations and by the aid of few physical concepts and pure geometrical relationships, the author succeeds in solving, in a natural, speedy, and elegant manner, problems of marked complexity. In certain cases, the method is almost without rival.

D. B. HALL,[30] Assoc. M. Am. Soc. C. E. (by letter).—In this paper the author further demonstrates, by new applications, the usefulness of his conception of the elastic curve as a traverse.[2] The first requisite in applying the methods of this paper, or in developing and applying still different methods, is a thorough grasp of this principle. The property of the traverse used in the paper (which makes it at once so simple and yet effective for solving continuous structures, and which has been extensively used but not explicitly stated by the author), is this: In a traverse such as Fig. 18, Angles *a* and *d* measure the rotations at the ends of the member; and, Angles *b* and *c* measure the moments at the ends of the member. Thus, the simple geometrical relationship among these four angles fully defines the elastic properties of the beam as it acts in a structure.

---

[30] Designer, Ash-Howard-Needles & Tammen, New York, N. Y.

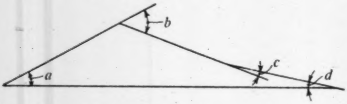

FIG. 18

The author has mentioned the fact that many complicated structures may be analyzed by considering only the members in the vicinity of any particular point, but he has devoted his paper mainly to exact solutions, as was appropriate for purposes of demonstration. From a practical standpoint the approximate solutions may be the more important.

Consider the closed box in Fig. 5. If End *B*, of Member *BC*, is given a rotation of 1, regarding it as the free end of a four-span structure, and then the traverse is traced all the way around to Point *B* in Member *AB*, the rotation at that point will be 142, and the moment, 1 × 246. Although a theoretical analysis of the structure should take into account the net rotation of Member *BA* with respect to Member *BC*, it is evident that, for all practical purposes, the stiffness of Member *BA* is $\frac{246}{142}$. The stiffness of Member *BC* found similarly by starting with a unit rotation at Point *B* in Member *BA*, is $\frac{2 \times 123}{74.5}$. It may be of academic interest, but it is scarcely worth remembering, that the true relative stiffness factors are $\frac{246}{141}$ and $\frac{2 \times 123}{73.5}$, since the rotation of one member with respect to the other is 1 less than its absolute rotation. Using one less span each way (that is, going around clockwise from *C* to *B*, or counter-clockwise from *A* to *B*) gives, for Member *B A*, $\frac{45}{26}$; and, for Member *BC*, $\frac{2 \times 33}{20}$, values which differ from the preceding by about 1 per cent. Thus, although a theoretically exact solution for the closed box required quite a little ingenuity, a practically exact solution presents no special difficulty.

RALPH W. HUTCHINSON,[31] ASSOC. M. AM. SOC. C. E. (by letter).—The relative flexure method of analyzing continuous structures presents a direct solution of these structures which may be applied efficiently to continuous-span bridges. Since haunched and tapered beams are used freely in continuous bridges, the determination of the properties of the members becomes an important detail of the analysis. Many computers use prepared charts or tables to obtain the properties of these beams for use with the familiar methods of analysis. The lack of such charts prepared for the relative flexure method need not discourage the use of the method as a tool because, by simple interrelations, the position of the points of inflection and the stiffness factors of haunched and tapered beams may be obtained quickly from the tables and charts in common use for obtaining the properties of these beams, which are used in connection with the method of end-moment distribution.

---

[31] Associate Bridge Engr., State of California, Sacramento, Calif.

When a moment is applied to one end of a beam which is hinged at the other end, the ratio of the rotation at the opposite ends of the beam is the carry-over factor, γ. Furthermore, $\frac{x\,l}{l - x\,l} = \gamma$; or, $x = \frac{\gamma}{1 + \gamma}$, which locates the point of inflection. For the same beam the angle of flexure, Δ (Fig. 19), is the sum of the rotations of the two ends of the beam and is equal to $(1 + \gamma)\,\theta_L$ in which θ_L is the rotation at the applied moment.

Inversely, the stiffness for flexure, $K\,F = \frac{K\,C}{1 + \gamma}$, in which the product, $K\,C$, is the stiffness of a free-ended beam as used in end-moment distribution. Furthermore, for symmetrical beams the stiffness, $K\,F = K\,(1 - \gamma)$, in which K is the stiffness of the fixed beam as used in end-moment distribution. For tapering beams there will be two carry-over factors and, therefore, two stiffness factors and the points of inflection will not be symmetrical.

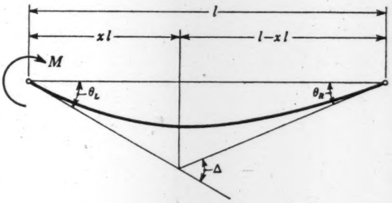

FIG. 19

Using the charts prepared by Thor Germundsson, M. Am. Soc. C. E.,[32] in 1932, the properties of the haunched beams from the author's illustrated example, Fig. 4(*a*), can be readily obtained. From the charts $\gamma = 0.71$; and, $K\,C = 6.2$. The point of inflection is at $x = \frac{0.71\,l}{1.71} = 0.415\,l$, which checks the value of $0.41\,l$ given by the author. The stiffness factor, $K\,F = \frac{6.2}{1.71} = 3.62$. The actual stiffness is $\frac{3.62 \times 2.25^3}{54} = 0.765$ or, as stated by the author, the relative $\Delta = \frac{M}{0.765} = 1.308\,M$, which checks the value of $1.292\,M$ given by the author.

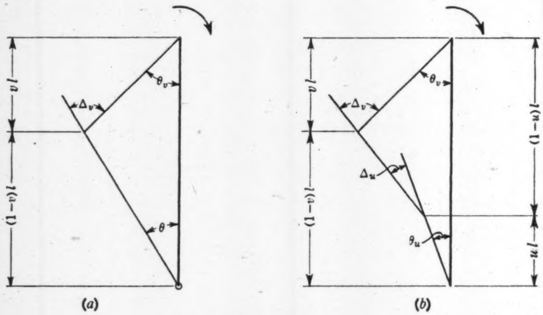
The relative flexure method is most efficient when applied to a series of continuous spans on flexible piers which are subject to moving loads. For analyzing a structure of this type the method appears to be faster than any other. For continuous spans on stiff piers it requires the introduction of another flexure system, that of the pier, and thus becomes inferior to the end-moment distribution method which gives moments in the piers from the beam moments without additional effort or complications. Hinged beams can also be solved readily by end-moment distribution with no more effort than that required for a solid beam whereas the solution by the relative flexure method appears to be excessively cumbersome.

---

[32] *Civil Engineering*, October, 1932, p. 647.

The case of continuous spans on flexible piers appears to the writer to be the only one in which the relative flexure method has any advantages over the common methods of solution. It is the writer's opinion that only those computers who frequently handle this type of structure should attempt to master the method. Those who work with this type of structure infrequently can best solve it by one of the methods with which they are already familiar.

ARTHUR B. McGEE,[33] ESQ. (by letter).—The analysis of partial fixture, in this paper, is very brief. Partial fixture of a member with variable moment of inertia, and treatment of a moment applied to the frame at a point of partial fixture, are not included.



(a) (b)

FIG. 20

The writer prefers to omit the idea of an imaginary member and deal directly with the angle of rotation of the partially fixed end. Fig. 20(*a*) shows a "traverse of the elastic curve" of a member with variable moment of inertia, hinged at the lower end. Fig. 20(*b*) shows a traverse of the same member with the lower end partially restrained. The terms, u and v, are identical with those same terms in the tables by Walter Ruppel, Assoc. M. Am. Soc. C. E.[34] The fixture factor, r, as used herein, is defined by:

$$r = 1 - \frac{\theta_u}{\theta} \qquad (14)$$

in which θ is the angle of rotation of the hinged end, and θ_u is the angle of rotation of the restrained end (see Fig. 20). When the end is hinged, θ_u equals θ and $r = 0$. When the end is fixed, $\theta_u = 0$ and $r = 1$. The fixity thus varies from 0 (hinged) to 1 (fixed); 75% fixture means that $r = 0.75$ and the partially fixed end rotates through one-fourth the angle of a hinged condition.

---

[33] Structural Engr. in Bridge and Structural Design Div., Bureau of Eng., City of Los Angeles, Los Angeles, Calif.

[34] *Transactions*, Am. Soc. C. E., Vol. 90 (1927), pp. 167–187.

To draw a traverse involving partial fixture and to evaluate the angles, it is only necessary to find the relation of θ_u to Δ_u (Fig. 20(b)). From Fig. 20(a):

$$\theta = \frac{v\,l}{(1 - v)\,l}\,\theta_v = \frac{v}{1 - v}\,\theta_v \ldots\ldots\ldots\ldots\ldots\ldots (15a)$$

from Fig. 20(b):

$$\theta_v \times v\,l = \theta_u\,(1 - v)\,l + \Delta_u\,[(1 - v)\,l - u\,l] \ldots\ldots\ldots (15b)$$

and,

$$\theta_v = \frac{1 - v}{v}\,\theta_u + \frac{1 - v - u}{v}\,\Delta_u \ldots\ldots\ldots\ldots\ldots (15c)$$

Substituting θ_v in Equation (15a):

$$\theta = \theta_u + \frac{1 - v - u}{1 - v}\,\Delta_u \ldots\ldots\ldots\ldots\ldots\ldots (15d)$$

and, substituting θ in Equation (14):

$$\frac{\theta_u}{\Delta_u} = \frac{(1 - u - v)\,(1 - r)}{(1 - v)\,r} \ldots\ldots\ldots\ldots\ldots\ldots (16)$$

Equation (16) is the general formula of the relation between the angles, θ_u and Δ_u. A member with a uniform moment of inertia has values of u and v equal to $\frac{1}{3}$, and Equation (16) is simplified to,

$$\frac{\theta_u}{\Delta_u} = \frac{1 - r}{2\,r} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (17)$$

which is the same formula as that given in Mr. Stewart's paper. When a moment is applied at a partially fixed end, a part of the moment is taken directly by the support and may be treated as a fixed-end moment not affecting any other joint in the frame. The part of the moment that is not taken by the support goes back into the frame. It is not necessary to make a traverse starting from the point of partial fixture to distribute this moment. Merely transfer this moment to the far end of the member by multiplying it by $\frac{v}{1 - v}$, the usual carry-over factor, and subtracting or adding the result to the existing moment at the far end, depending on whether there is an odd number or an even number (including zero) of points of inflection between the ends.

The problem shown in Fig. 21(a) will now be worked in detail. Fig. 21(b), (c), (d), (e), shows the properties of the members. Each Δ equals the area of an $\frac{M}{E\,I}$-diagram. Thus, in the traverse an angle represents an area. The formulas for Δ may be found in a discussion by Fang-Yin Tsai, Assoc. M. Am. Soc. C. E.[35] The values of u, v, p, and q are taken from Ruppel's tables.[34] In Fig. 21(a) the length of Member $C\,D$ is 20; and in Fig. 21(d) and Fig. 21(e): $u = 0.250$; $v = 0.427$; $p = 0.292$; and $q = 0.171$. In Fig. 22(a) apply an unknown moment at Joint B as shown by the arrow. Rotate Joint B and start drawing the traverse from that point, progressing both ways to Points A and D. Angle points occur at each corner and opposite each center of gravity of the $\frac{M}{E\,I}$-diagrams. The lines of the traverse are tangent to the elastic curve at the joints, but the middle section on each side is not tangent to the elastic curve. The numbers in parentheses are moments; the other numbers are angles; and, ratios of Δ-angles to moments are given in Fig. 21(b), (c), (d), (e).

FIG. 21

Solving Equation (16) gives $\theta_u = 1.691\,\Delta_u$. Now, start at Point D letting θ_u, the angle of rotation, equal 1.691 and the next angle, 1. Then, $1 \div 0.292 = (3.425)$; $[1.691 \times l + 1 \times (0.427 + 0.323) \times l] \div 0.427 \times l = 5.717$; $5.717 - 1 - 1.691 = 3.026$; $5.717 \div 0.171 = (33.433)$; $33.433 \times 0.4 = 13.373$; $13.373 \times 1 + 3.026 \times 2 = 19.425$; $19.425 + 13.373 + 3.026 = 35.824$; $35.824 \div 0.4 = (89.56)$; $19.425 \times 2 = 38.85$; $38.85 \div 1.5 = (25.90)$; $19.425 \div 1.5 = (12.95)$; and, $25.90 + 89.56 = (115.46)$.

FIG. 22

The traverse in Fig. 22(b) is drawn in a similar manner. Begin assigning angle values at End A and progress to Corner C whose angle of rotation is found to be 2.533. The angles from Point C to Point D must be proportional to those in Fig. 22(a) since $\frac{\theta_u}{\Delta_u} = 1.691$ as before. Therefore, the angles will be $\frac{2.533}{3.026}$ times the values in Fig. 22(a).

Fig. 23(*a*) shows the frame deflected sidewise with the top member straight and both legs fixed at the bottom. The deflection, δ, is the same in each leg so that the relative moments may be found for this condition. End *D*, however, being only 25% fixed will have a value of $0.25 \times 530 = 132.5$; $0.75 \times 530 \times \frac{v}{1 - v} = 296$, which is carried over to End *C*, and, $905 - 296 = 609$, the moment at End *C* when End *D* is 25% fixed. These moments are shown on the frame in Fig. 23(*b*). Now, Member *B C* is allowed to deflect; and, the moment at Joint *B* is distributed by using $\frac{66.7}{115.46}$ of the moment values in Fig. 22(*a*) and the moment at Joint *C* is distributed by using $\frac{609}{38.165}$ of the moment values in Fig. 22(*b*). Signs of the moments are readily seen by referring to the arrows on the traverses, clockwise being positive. The arrows are always placed so that they tend to straighten the elastic curves. Shears in the legs of Fig. 23(*b*) now show the moments to be due to a horizontal force of 18.27. Therefore, multiply all moments by $\frac{1\,000}{18.27}$ and find the moment at End $A = 3\,822$; Joint $B = 3\,994$; Joint $C = 9\,934$; and End $D = 4\,855$.

FIG. 23

From preference, the writer has been using the Stewart traverse method since about 1936, for continuous and rigid frame bridges.

E. NEIL W. LANE,[36] JUN. AM. SOC. C. E. (by letter).—The use of relative flexure factors in the analysis of continuous structures, as described by Mr. Stewart, is simple and fundamental in theory. It is a general method for attacking the solution of moments in rigid frameworks that is particularly valuable for use in conjunction with moving and variable load systems. Combining bending moments by superimposing influence diagrams aids in visualizing the elastic behavior of a structure. Moreover, the process is quite time-saving.

The author's method somewhat parallels the steps in the slope deflection method in that the process is indirect. Angles are found first, and then substituted in the original equations to obtain the desired moments. Similarly, the author borrows from moment distribution in his procedure of correcting for side-sway. Trial moments are found first, to which corrections are added to satisfy statics.

---

[36] Junior Engr., U. S. Dept. of Interior, National Park Service, Eng. Div., Omaha, Nebr.

In solving for moments under a single fixed condition of loading, the writer prefers the method known as traversing the elastic diagram that was published by the author in 1934.[37] The method of relative flexure factors is an outgrowth and adaptation from the previous paper. It is believed that the evolution of the new method will be of interest. As a means of widening the scope of the

[37] "Analysis of Continuous Structures by Traversing the Elastic Curves," by Ralph W. Stewart, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 105.

author's present work, an example has been chosen to show the solution for moments in a frame with sloping members (see Fig. 24(*a*)).

The solution by the original method requires eight equations, the first of which traverses the elastic diagram:

$$\theta_A + \Delta_1 + \Delta_2 - A_1 + \Delta_3 + \Delta_4 - \Delta_5 = 0 \ldots\ldots\ldots\ldots (18)$$

in which, $A_1 = 0.00307$ radians. Equation (18) is analogous to others frequently used in elastic energy theory.[38] The next two equations are statements of relative stiffness:

$$\Delta_1 \left(\frac{900}{258.5}\right) = \Delta_2 \left(\frac{10\,000}{304.6}\right) \ldots\ldots\ldots\ldots (19a)$$

and, $M_{CB} = 384\,000 + M_{CD}$; or,

$$\Delta_3 = 0.000194 + 2.26\,\Delta_4 \ldots\ldots\ldots\ldots (19b)$$

The vertical deflection of Point *A* relative to Point *C* is zero:

$$32\,\theta_A + 26\tfrac{2}{3}\,\Delta_1 + 16\,\Delta_2 - 10\tfrac{2}{3}\,A_1 + 8\,\Delta_3 = 0 \ldots\ldots\ldots (19c)$$

The horizontal deflection of Point *A* relative to Point *D* is also zero:

$$-13\tfrac{1}{3}\,\Delta_1 - 22\tfrac{2}{3}\,\Delta_2 + 24\tfrac{4}{9}\,A_1 - 25\tfrac{1}{3}\,\Delta_3 - 18\tfrac{2}{3}\,\Delta_4 + 9\tfrac{1}{3}\,\Delta_5 = 0 \ldots (19d)$$

Now, to obtain the sixth equation, three member equilibrium equations must be solved simultaneously. These are: $M_{CD} + M_{DC} - 336\,H = 0$, or,

$$10^6\,(\Delta_4 + \Delta_5) - 0.0752\,H = 0 \ldots\ldots\ldots\ldots (19e)$$

$M_{BC} - M_{CB} + 96\,H - 288\,V_A + 96 \times 10^5 = 0$; or,

$$10^6\,(\Delta_2 - \Delta_3) + 0.0485\,H - 0.1455\,V_A + 4\,850 = 0 \ldots\ldots (19f)$$

and, $M_{BA} - 240\,H + 96\,V_A = 0$; or,

$$10^6\,\Delta_1 - 1.153\,H + 0.461\,V_A = 0 \ldots\ldots\ldots\ldots (19g)$$

Slide-rule values give $H = 12.3$ kips; $V_A = 25.9$ kips; and, $M_{DC} = -62.3$ ft-kips.

By using relative flexure factors the moment coefficients, as shown in Figs. 24(*b*), 24(*c*), and 24(*d*), are obtained. These are relative moments, immediately adaptable and easily checked for any system of loading. The moments, uncorrected for side-sway, are shown in Fig. 24(*e*). By the foregoing procedure, Equations (18), (19*a*), and (19*b*) have been eliminated and the problem simplified. The true moment at the end of each member will consist of the uncorrected moment, plus or minus some correction. Let these corrections be: *X* at Point *B*; *Y* at Point *C*; and, *Z* at Point *D*. Then, the solution of the remaining five equations will furnish the desired results. Equations (19*e*), (19*f*) and (19*g*) then become,

$$16\,220 - 0.00298\,Y - 0.00298\,Z - H = 0 \ldots\ldots\ldots\ldots (20e)$$

$$60\,440 - 0.01042\,X = 0.01042\,Y + H - 3.0\,V_A = 0 \ldots\ldots (20f)$$

---

[38] "Elastic Energy Theory," by J A. Van den Broek, M. Am. Soc. C. E. (1931), p. 81, Equation III.

and,

$$910 - 0.00417\,X - H + 0.40\,V_A = 0 \qquad (20g)$$

For convenience, Equations (19*c*) and (19*d*) were replaced. The fourth equation is a statement of a statement of moments about Point D: $M_{DC} + 9\,216\,000 - 384\,V_A = 0$; or,

$$28\,730 - 0.00261\,Z - V_A = 0 \qquad (21a)$$

The fifth formula is a statement equating the vertical deflection of Point A when released to the opposite deflection caused by the redundant reaction:

$$1.372 + 0.00484\,X + 0.00278\,Y - 0.00133\,Z = 0 \qquad (21b)$$

This is a means of correcting for side-sway in any frame.

It is worth while to note that the elastic energy theory probably furnishes the most simple and direct solution for this type of problem. When used with area moments, Equation (21*b*) becomes:

$$0.212\,V_A - 0.385\,H - 0.00103\,M_{DC} - 2.19 = 0 \qquad (22a)$$

Using a statement of horizontal deflections similar to Equation (22*a*):

$$0.288\,V_A - 0.594\,H - 0.00024\,M_{DC} - 1.19 = 0 \qquad (22b)$$

The use of Equations (21*a*), (22*a*), and (22*b*) makes a much more desirable form of solution of problems of this nature than the method proposed by the author. The writer does believe the method of relative flexure factors to be an improvement over the procedure published by Mr. Stewart in 1934 for use in analyzing continuous beams and frameworks not subject to side-sway.

RALPH W. STEWART,[39] M. AM. SOC. C. E. (by letter).—In presenting a new approach to the analysis of continuous structures it cannot be expected that the profession will adopt it quickly. The writer feels gratified, therefore, that of those contributing discussion several engineers have endorsed the method for the class of structures treated.

Mr. Shapiro thinks that the unpublished method of "transmission coefficients"[9] is the best for all-round use. By private correspondence with Mr. Shapiro the writer obtained a solution of Fig. 25,[40] by the method of transmission coefficients and found that the number of arithmetical operations necessary to solve it by that method was greater than by the method of relative flexure factors; and that the former method lacked the automatic checks and valuable by-products offered by the latter method.

The direct construction by Mr. Peterson of influence lines for both moments and shear, and also for yielding supports by using a traverse of the elastic curves in connection with the Müller-Breslau relationship between influence lines and elastic curves, is a valuable addition to the paper. Any computer who wishes to avoid the graphical construction of funicular polygons to obtain the ordinates of the final elastic curves can use the following formula which, for beams of constant section, expresses the ordinates to the elastic curves in terms of the end slopes:

---

[39] Engr. of Bridge and Structural Design, City of Los Angeles, Los Angeles, Calif.

[40] "Analysis of Continuous Frames by Distributing Fixed-End Moments," by Hardy Cross, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 96 (1932), Fig. 1, p. 5.

$$\text{Ordinate} = (\theta_1\, k_1\, k_2^2 + \theta_2\, k_1^2\, k_2)\, l \ldots\ldots\ldots\ldots\ldots (23)$$

in which θ_1 and θ_2 are the left and right end slopes respectively, and k_1 and k_2 the fractions of the beam length from the left and right ends respectively.

The computation and tabulation of ordinates from this formula will be less laborious to most computers than the graphical construction.

Mr. Housner objects to considering the length of the base of a traverse triangle as equal to the lengths of the two inclined sides. If the validity of the traverse method of treating elastic structures is rejected on this account, it will be necessary also to reject the classic theory of flexure which neglects the difference between the abscissa of a point in a beam and the diagonal distance to the same point after the beam is deflected. Textbooks on flexure are based on the radius of curvature of a flexed beam being taken as

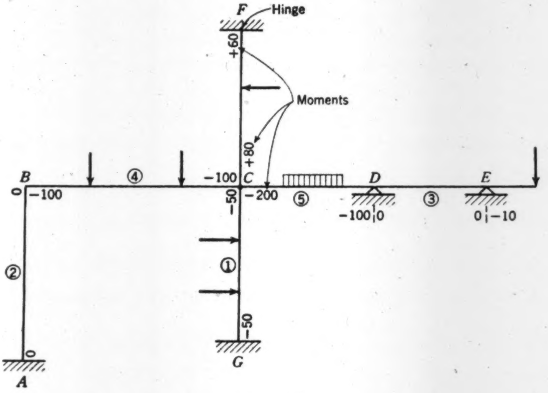

FIG. 25

$$r = \frac{(dl)^3}{dx\, d^2y} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

Treatises on the calculus show that the radius of curvature is

$$r = \frac{\left[1 + \left(\frac{dy}{dx}\right)^2\right]^{\frac{3}{2}}}{\frac{d^2y}{dx^2}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

An attempt to reduce Equation (25) to Equation (24) will disclose a point in the treatment of flexure used in all texts to which Mr. Housner's objections would be applicable. The value of an infinitesimal, or nearly infinitesimal, angle may be taken as equal to the value of either its sine or its tangent. In stress computations for bridges and buildings it is entirely proper and customary to consider the angles due to elastic deformation as conforming to the law of infinitesimal quantities, as is done in this paper.

The illustration by Professor Wilbur that for a continuous beam the same set of arithmetical computations used in the writer's paper can be applied in connection with the moment-area method is correct. However, the extension of the moment-area delineation to more complex problems will give rise to difficulties, whereas the traverse delineation will make it easy for the computer to keep account of what he is doing. Mr. Hadley's complimentary statements about the flexure-factor method are very pleasing. Mr. Blog gives interesting general comments and opinions on various methods of analyzing continuous structures. As time passes and new literature is published the rating of these various methods will become determined more accurately. Messrs. Mitchell, Floris, Hall, and McGee endorse the flexure-factor method for one-story structures, and all have done constructive work to expand the scope of the paper. The statement of Mr. Mitchell that for continuous beams the three-moment theorem and end-moment distribution cannot compare with the flexure-factor method, and the statement of Mr. McGee that he has adopted the method for rigid frames, are very gratifying.

The solution by Mr. McGee of a laterally loaded unsymmetrical frame with one partly fixed pier base supporting a tapering pier is an interesting illustration of the utility of the flexure-factor method. This solution is worth saving for reference, not only on account of the problem but also because of the complete exposition of the method of adopting the Ruppell tables[34] to an elastic curve traverse.

Mr. Hutchinson expresses an opinion that the relative flexure-factor method is advantageous only for continuous spans on "flexible piers," and that in cases in which the elastic properties of the piers must be considered, or in which a hinge occurs in a span, the method is less convenient than other methods. According to studies by the writer and others, the inclusion of elastic piers adds no more to the work of computation than if methods other than the flexure-factor method are used. If side-sway can be neglected it adds less work to include piers in a flexure-factor analysis than to include them in a moment distribution or slope deflection analysis. It is also easy to traverse across a hinged span as the following solution will demonstrate. Fig. 26 represents the same continuous beam as Fig. 2 except that a hinge has been introduced at the third-point of Span $B\,C$. The original $\frac{I}{l}$-value for this span was 4. After inserting the hinge the $\frac{I}{l}$-values of the two fractional parts will become 12 and 6, as shown.

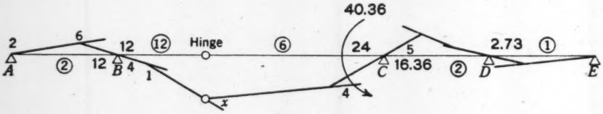

FIG. 26

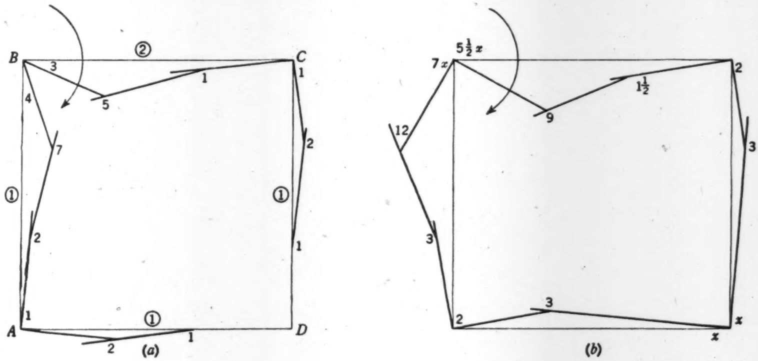
By statics, the relationship of M_{BC} to M_{CB} must be in proportion to the distances of Points B and C from the hinge, or as 1 : 2. Dividing by the stiffnesses, the ratio of the corresponding Δ-angles is as 1 to 4. Write these relative Δ-values on the figure; multiply them by the stiffnesses to get the relative moment values; designate the angle at the hinge by x; balance the moment of 12 with M_{BA} also equal to 12; and write the angle values appurtenant to $M_{BA} = 12$, in Span A B. For convenience, consider Span B C as divided into nine equal units of length. The usual type of traverse equation then gives $(4 \times 9) + (1 \times 8) - 6\,x - (4 \times 2) = 0$; and $x = 6$. Combining angles from Points B to C gives $\theta_c = 5$.

The resisting moments in Spans C D and D E will now be $\frac{5}{11}$ times those in Fig. 2. Write these in the figure, add the two resisting moments at Point C to get the activating (fixed-end) moment of 40.36 at Point C, and the picture of the flexure is complete with all moments and rotations given. If the hinge is placed at one-seventh of the distance from Point B to Point C (which is the point of contraflexure in Fig. 2(*e*)) the angle x will be found by the foregoing procedure to be zero, and the hinge will be without effect on the moments in the structure. This form of analysis will enable the computer to determine the desirable location for a hinge more quickly than by other forms.



(*a*) (*b*)

FIG. 27

Mr. Hall's solution of the closed box illustrates very well how an exceedingly accurate approximation of the bending moments can be obtained by a simplified application of the method. Although it is as exact as the common theory of flexure, the solution given in the paper involves the somewhat troublesome mental effort of carrying computations along the figure with each angle expressed as a two-term quantity. After further study the writer has concluded that most computers will find it easier to make two separate computations for this structure, using a single term for each angle. This is done as follows:

In Fig. 27(*a*), consider rotation as zero at Joint D and draw a traverse D C B due to the moment M_{BC} as shown, ending with a joint rotation of 3 at Point B. Now, with the moments about Joint D in balance, begin at D and draw the traverse $D\ A\ B$, as shown, ending with a joint rotation of 4 at Point B. To equalize these joint rotations at Point B it is obvious that Joint B, and consequently Joint D, must rotate in clockwise direction. Therefore, draw Fig. 27(*b*), in which Joint D is without restraint and has clockwise rotation equal to x. Numerals in this figure are coefficients of x. Now, combining Figs. 27(*a*) and 27(*b*), since Rotation $B\ A$ must equal Rotation $B\ C$: $7\,x - 4 = 5\frac{1}{2}\,x + 3$; and $x = 4.667$, which checks Fig. 5.

FIG. 28

This treatment can readily be extended to multiple box openings, the solution involving one pair of simultaneous equations at each intermediate vertical member. To illustrate this case the traverse in Fig. 28(*a*) is drawn from Point E to Point C and from Point E to Point F, letting Point E be fixed and balancing the moments about Point E. To close the traverse along Member CF: $(3 \times 3) - 2x + y = 0$; and $-3 + 2y - x = 0$. Solving, $x = 7$; and $y = 5$.

The remainder of the solution involves nothing that has not already been explained. Bending moments not necessary for the computation are omitted from Figs. 28(*a*) and 28(*b*), for simplicity. Any omitted moment may be added to the figure at once by multiplying its Δ-angle by the stiffness factor of the member.

Mr. Lane's solution of an unsymmetrical frame with a sloping column is of interest. It avoids the use of trigonometric functions which were applied to the solution of the same type of problem by Mr. Mitchell. His statement that the flexure-factor method is time saving is appreciated.

In conclusion it may be stated that the method of flexure factors based on a traverse of the elastic curves is not as restricted in its scope as some of the discussion indicated. It can be extended to curved beams and arch analysis. For arch analysis the Δ-angles are not in the unsprung axes of the curved members but are at the intersections of those end slope tangents which are selected to control the design. The ordinates of these Δ-angles can be computed, and by using the Δ-angle points as centers of rotation, the usual arch formula can be computed. Some of this extension work might be suitable for college theses.

DEOXYGENATION AND REOXYGENATION

By C. J. Velz,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Earle B. Phelps and C. J. Velz.

Synopsis

Too frequently, sewage disposal is thought of as synonymous with discharge into the nearest body of water. Such is not the case. Ultimate disposal (that is, final oxygen equilibrium) is inescapable and if it does not occur, at least partly, before the effluent is discharged, the sewage becomes a stream liability. The public is fast becoming impressed with the fact that it must be concerned with this problem beyond the sewer outlets. There is a general awakening and a demand that something be done about the menace and nuisance of stream pollution.

With advances in the knowledge and art of treatment permitting the reduction of almost any waste burden, the remedial problem is largely one of procedure and financing. If economy in efforts and funds were of no consequence, the problem could be solved simply by the invariable application of the highest and most elaborate treatment known. A sound and economical solution, however, requires an evaluation of pollution liabilities and stream assets, in advance of building, to permit the determination of the effect upon the stream of any proposed remedial program.

In design it is highly important to give careful consideration to plant details and mechanical efficiency, but in the enthusiasm over the development of the "means" one should not lose sight of the "end." First and foremost in importance is the effect of the design on the stream.

A technique for stream analysis is presented in this paper which is easy and rapid to apply and should serve as an aid in determining where, when, and how much to build, and what degree of treatment to provide.

Notation.—The introduction of some change in letter symbols is due to an effort to avoid conflict with standard symbols in allied fields of study.

Note.—Presented at the meeting of the Sanitary Engineering Division, New York, N. Y., January 21, 1937, and published in April, 1938, *Proceedings*.

[1] Prof., San. Eng. and Head, Civ. Eng. Dept., Manhattan Coll., New York, N. Y.

INTRODUCTION

Nuisance in streams is a combination of noxious conditions. Although no single measure fully reflects all these conditions, oxygen content of the stream is the most inclusive and best single index of the degree of pollution. Deoxygenation is a complex bio-chemical process influenced radically by time, temperature, and the nature of waste. Reoxygenation, no less complex, is primarily a chemical process, influenced radically by concentration of dissolved oxygen, time, temperature, depth, and turnover. Professor Earle B. Phelps and H. W. Streeter, M. Am. Soc. C. E., have integrated these factors into a single expression for resultant oxygen, as defined by the well-known formula:[2]

$$O_t = \frac{k\,O_{0d}}{K - k}\left(e^{-kt} - e^{-Kt}\right) + O_0\,e^{-Kt} \ldots\ldots\ldots\ldots\ldots (1)$$

in which: O_0 = initial dissolved oxygen saturation deficit of the water, in parts per million; O_t = saturation deficit, in parts per million, after time, t; O_{0d} = initial oxygen demand of the organic matter of the water, in parts per million; k = coefficient defining rate of deoxygenation; K = coefficient defining rate of reoxygenation; t = elapse of time, in days; and e = Naperian base.

An integrated formula such as Equation (1) has many advantages but, owing to its complexity and the many factors involved, is subject to the dangers of misunderstanding and misapplication. In certain instances, a better understanding and wider application of the fundamentals can be obtained by breaking down these complexities and considering deoxygenation and reoxygenation separately.

REOXYGENATION

The most important asset of a stream is the natural process of reoxygenation—that is, its absorption of oxygen from the atmosphere. Without it the entire world would long ago have been faced with complete treatment, or sewage everywhere would have to be disposed in deep sea water. Fortunately, reoxygenation is a gift of Nature. It is important in the pollution problem that this natural asset be evaluated because economics demands that it be used wisely.

As early as 1910, in his studies of the pollution of New York Harbor, Professor Phelps[3] established a fundamental basis for an evaluation. He considered reoxygenation as a separate phenomenon governed by two fundamental laws: (1) The law of rate of solution; and (2) the law of diffusion. The rate of absorption is inversely proportional to the concentration of dissolved oxygen; and the rate of diffusion through water and between two proximate points is proportional to the difference in concentration at these two points. With these two fundamental laws and his experimental determination of the coefficient of diffusion in quiescent water, Professor Phelps developed the formula for absorption of oxygen:

$$O_t' = 100 - \left(1 - \frac{O_{0d}'}{100}\right) \times 81.06\left(0.779^{c} + \frac{0.105^{c}}{9} + \frac{0.0019^{c}}{25}\cdots\right)\ldots (2)$$

---

[2] "A Study of the Pollution and Natural Purification of the Ohio River: III, Factors Concerned in the Phenomena of Oxidation and Reaeration," *Public Health Bulletin No. 146*, U. S. Public Health Service, 1925.

[3] "Location of Sewer Outlets and Discharge of Sewage into New York Harbor," Rept. by the late Maj.-Gen. William Black, U. S. Army (*Retired*), and Prof. Phelps, 1910.

in which O_{0d}' = initial dissolved oxygen expressed as the average content in percentage of the saturation value; O_t' = final dissolved oxygen expressed as the average content in percentage of the saturation value; and c = a constant for each set of conditions and equal to,

$$c = \frac{\pi^2 a t}{d^2} \qquad (3)$$

in which t = time of exposure, in hours; d = depth of water, in centimeters; and, a = a diffusion coefficient which, in turn, is a function of temperature.

From an analysis of Professor Phelps' experimental determination of diffusion coefficient, the writer develops the relationship between the coefficient and temperature represented by the formulas:

$$\log a = 0.04125\, T - 0.672 \qquad (4)$$

or,

$$a = 1.42 \times 1.1^{(T-20)} \qquad (5)$$

in which T = temperature, in degrees Centigrade. It is apparent from the graphical representation shown in Fig 1 that there is linear relationship between the log of the coefficient of diffusion and temperature.

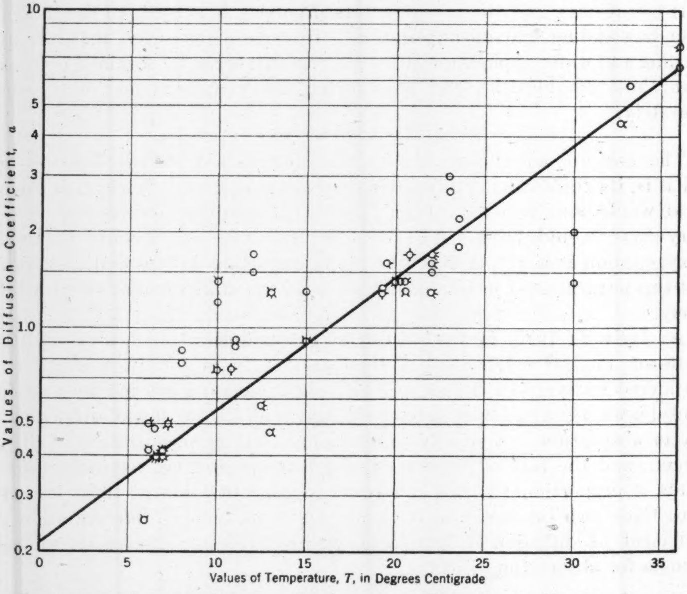

FIG. 1.—RELATIONSHIP BETWEEN DIFFUSION COEFFICIENT AND TEMPERATURE (DEGREES CENTIGRADE), BASED ON PHELPS' EXPERIMENTAL DATA

The fundamental relationships established mathematically and experimentally are applicable to actual stream conditions. For example, consider a flowing stream: The integration of the average oxygen content of a stretch of the stream is analogous to mixing the entire volume prior to exposure to the atmosphere. To maintain the integrated average oxygen content at a constant value (that is, along given profiles and contours) by the equilibrium established between deoxygenation and reoxygenation, is analogous to considering the body of water quiescent in so far as movement on a horizontal plane is concerned. As long as that equilibrium is maintained the initial oxygen deficit remains constant, deoxygenation factors utilizing oxygen just as fast as, but no faster than, the water absorbs oxygen from the atmosphere. Under such conditions the quantity of oxygen absorbed in any given time is dependent only upon the frequency of vertical mixing—the stream turnover. Thus, by substituting the factors in Equation (2), using time of exposure, t, as the interval between vertical mixes, the oxygen absorbed by the river stretch is obtained. Under the conditions of equilibrium maintained, the same quantity will be absorbed in each succeeding mixing interval. Hence, Professor Phelps' integrated equation expressing total quantity, in actual application becomes a differential equation expressing rate of absorption. The only factor not readily measurable in the stream is frequency of vertical mixing, which, for the most streams, falls between relatively narrow limits.

Equation (2) permits direct evaluation of the influence of depth, which, as is apparent from Equation (3), is a dominating factor. In Equation (1) all reoxygenation influences are combined into a single constant, K. The comprehensiveness of K is likely to lead to error when it is applied to streams other than the one for which it was evaluated, whereas, in Equation (2) cognizance is taken of the particular physical characteristics of each stream. Furthermore, Equation (1) is limited in application to inland waters. The complexities of tide-water flow which preclude the application of Equation (1) to brackish water, have been indicated in a paper on the pollution of New York Harbor written in 1932.[4] In practical application, the disadvantage of Equation (2) is the mathematics necessary to solve it. A large number of terms of the converging series, involving Exponent c must be used in order to obtain accuracy (40 to 60 terms, when the value of c is small). The writer has developed a graphical means of solution from which oxygen absorption, under any set of conditions, can be obtained accurately at a glance. By mathematics the process would require much painstaking effort.

STANDARD REOXYGENATION CURVE

From Equation (2) it is apparent that oxygen absorption is inversely proportional to initial concentration, or directly proportional to oxygen deficit $\left(1 - \frac{O_{0d}'}{100}\right)$. Furthermore, it is a function of the summation of a converging series involving time, depth, and a specific diffusion coefficient as an exponent, c, in each term of the series. By making O_{0d}' equal to zero (beginning with water devoid of oxygen), the summation of the series,

$$\Sigma s = 81.06\left(0.779^c + \frac{0.105^c}{9} + \frac{0.0019^c}{25} \cdots\right) \ldots\ldots\ldots\ldots (6)$$

represents the deficit at any time; or the deficit becomes a function of c.

---

[4] "Report on the Pollution of New York Harbor," by Earle B. Phelps and C. J. Velz, *Sewage Works Journal*, January, 1933.

A solution of the series for various arbitrary values of *c* provides a set of control points indicating the relationship between *c* and the deficit which, when plotted on natural scales, produces Fig. 2. The section of the curve most frequently applicable to actual stream conditions lies between values of *c* from 0.000001 to 0.001, for which accurate interpolation is not permitted by Fig. 2. In order to emphasize the range of the curve and particularly to provide a convenient means of evaluating *c* in terms of the factors by which it is influenced, the writer has developed the graphical representation shown in Fig. 3. It is at once apparent from this chart that for the most useful range of the curve there is linear relationship between the dissolved oxygen and the log of *c*, a very convenient relationship for interpolation and for conversion.

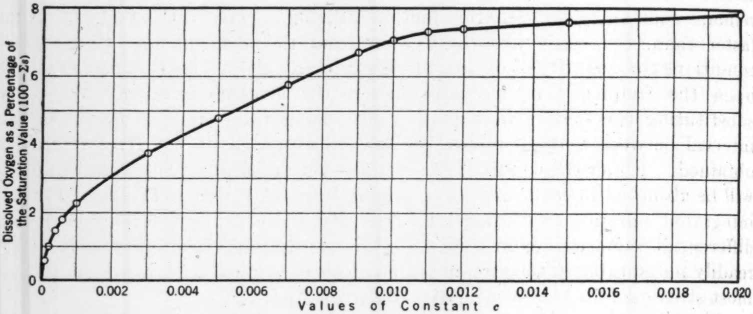

FIG. 2

In the evaluation of *c* in Equation (3), in terms of time, depth, and diffusion coefficient, including temperature, the writer has used the characteristics of a logarithmic scale adaptable in the principle of a slide-rule: Constant *c* is inversely proportional to the square of the depth, *d*, and directly proportional to time, *t*, and the diffusion coefficient, *a*. The diffusion coefficient, *a*, is a function of temperature as defined by Equation (5); and, since *c* is directly proportional to *a*, for each unit change in temperature, *T*, a fixed rate of change occurs in *c*. The use of the standard reoxygenation curve is illustrated by examples.

Example 1.—Given a stretch of stream in which the average depth, *d*, is 10 ft; the average temperature, *T*, is 24° C; the dissolved oxygen profile of the stretch is maintained constant at an integrated average of 40% of the saturation value; and the flow conditions were such as to produce a time of mix, *t*, of 15 min.

Referring to Fig. 3: (1) Opposite 10 ft on Scale (4) read 0.000151 on Scale (3); (2) slide the control point of Scale (8) to coincide with 0.000151 on Scale (3); (3) opposite $\frac{1}{4}$ hr on Scale (8) read 0.000038 on Scale (3); (4) slide the control point of Scale (7) to coincide with 0.000038 on Scale (3); (5) opposite 24° on

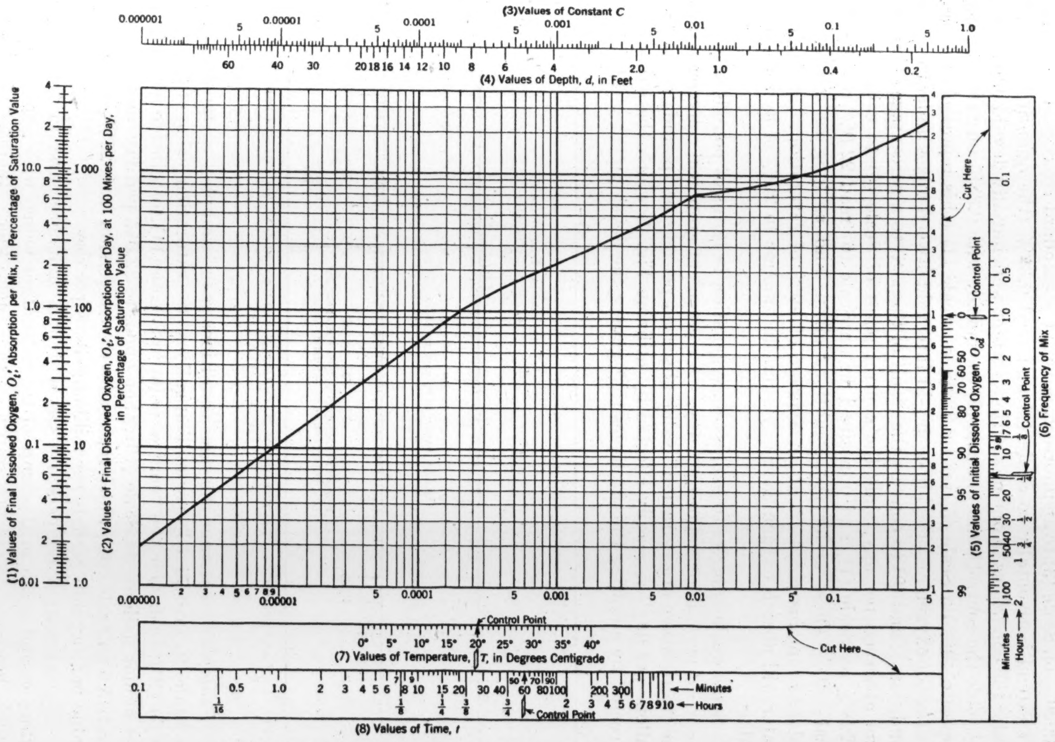

FIG. 3.—STANDARD REOXYGENATION CURVE, BASED ON BLACK AND PHELPS' FORMULA

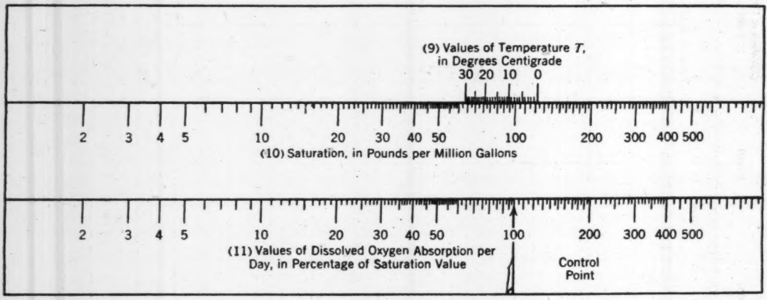
Scale (7) read 0.000055 on Scale (3) (this gives the value of the constant, *c*, at a depth of 10 ft, a mixing time of $\frac{1}{4}$ hr, and 24° C); (6) descend vertically from 0.000055 on Scale (3) to an intersection with the standard reoxygenation curve; (7) extend horizontally to Scale (1) and read 0.38% (the quantity absorbed under the conditions in one mix period if water were initially devoid of oxygen); (8), slide the control point of Scale (5) to coincide with 0.38% on Scale (1), and opposite 40% on Scale (5) read 0.228% on Scale (1) (this represents the percentage of oxygen absorbed in each $\frac{1}{4}$-hr interval between mixes under the given conditions); and (9) to convert the result of Step (8) to a percentage of saturation absorbed per day, slide the control point of Scale (6) to coincide with 0.228% on Scale (1), and opposite $\frac{1}{4}$ hr on Scale (6) read 22.0% per day on Scale (2). Thus, under the conditions given, and as long as the oxygen balance remains constant at an average of 40% of saturation, this body of water will absorb oxygen each day equal in amount to 22% of its saturation value.

Some workers prefer to express reoxygenation in terms of pounds of oxygen absorbed per million gallons per day. A convenient graphical conversion from the "percentage of saturation" value absorbed per day to "pounds per million gallons per day" is readily effected by utilizing Fig. 4, which the writer constructed by adapting the principles that govern the development of Fig. 3.



(9) Values of Temperature *T*, in Degrees Centigrade
30 20 10 0
2 3 4 5 10 20 30 40 50 100 200 300 400 500
(10) Saturation, in Pounds per Million Gallons
2 3 4 5 10 20 30 40 50 100 200 300 400 500
(11) Values of Dissolved Oxygen Absorption per Day, in Percentage of Saturation Value
Control Point

FIG. 4.—CONVERSION OF PERCENTAGE OF SATURATION VALUE PER DAY TO POUNDS PER MILLION GALLONS PER DAY

Example 2.—Assume the same conditions as in Example 1. Opposite 24° C on Scale (9) read 71.1 lb per million gallons (the saturation value at 24° C) on Scale (10); then slide the "control point" of Scale (11) to coincide with 71.1 lb per million gallons, on Scale (10); then opposite 22.0% per day, on Scale (11), read 15.6 on Scale (10), which represents the conversion from 22% of saturation value per day into pounds per million gallons per day.

Reoxygenation temperature has a double influence, first in the rate of diffusion and again in the limit of the saturation value, with opposite effects which, however, do not necessarily balance each other. Increase in temperature increases the rate of diffusion and, consequently, the rate of absorption, but the limit of quantity absorbed (namely, the saturation), decreases with increase in temperature.

VERIFICATION OF EQUATION (2)

An excellent check on Equation (2) and Fig. 3 is afforded by the experiments reported by H. W. Streeter and Chilton Wright, Members, Am. Soc. C. E., and Mr. R. W. Kehr in 1936.[5] By applying depth, time, and temperature values from these experiments to Fig. 3, a close agreement is noted between the dissolved oxygen computed and that observed in the experiments. Furthermore, if curves in the foregoing report[6] are replotted on a basis of percentage of saturation, beginning with initial oxygen devoidance, the time of turn-over, or frequency of mix, is obtained at the point where the dissolved oxygen coincides with that obtained by Fig. 3 at the same time interval.

The frequencies of mix computed by this method, at depths of 0.318 ft and 1.0 ft, indicate a relationship with the velocity shown in Fig. 5. It will be noted that the logarithm of the frequency of mix bears a linear relationship to velocity and, logically, as depth increases, the frequency of mix diminishes. Further controlled experiments extended to depths normally encountered in streams will doubtless lead to a set of curves similar to Fig. 5. In the absence of such a set of curves the writer has obtained satisfactory checks against observed dissolved oxygen profiles by using an average frequency of $\frac{1}{4}$ hr per mix, ranging from $\frac{1}{8}$ hr for shallow, rapidly flowing streams to $\frac{1}{2}$ hr for deep, slowly flowing streams.

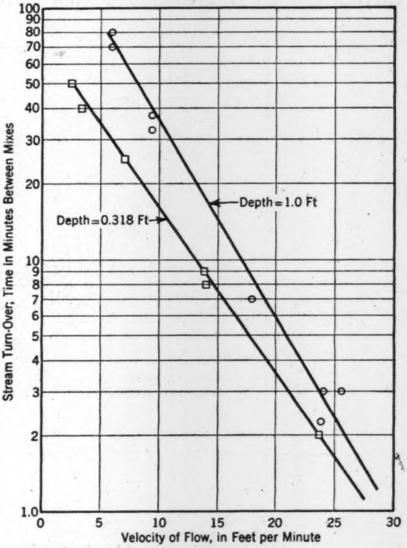


FIG. 5.—RELATIONSHIP BETWEEN STREAM TURN-OVER, VELOCITY, AND DEPTH

The experimental confirmation of Equation (2) and Fig. 3 under controlled conditions of flow and the close agreement between computed and observed dissolved oxygen values when applied to actual stream conditions, substantiate Professor Phelps' original fundamental assumptions. It is hoped that the advantages of simple, direct evaluation of reoxygenation for both inland and tidal waters will assist in routine stream-analysis technique as applied in the design of pollution remedial work.

DEOXYGENATION

The major pollution liability in streams is deoxygenation resulting from the satisfaction of the natural oxygen demand of organic waste matter. In the expression of his law, namely, that "the rate of biochemical oxidation of organic matter is proportional to the remaining concentration of unoxidized substance measured in terms of oxidizability," Professor Phelps changed the concept of pollution from that of a simple, static, chemical dilution phenomenon to one of changing, bio-chemical complexity. The law has been checked repeatedly by experiment and has been confirmed in actual observation of stream pollution studies; and can be incorporated, safely and advantageously, as routine technique in the design of remedial works. It is recognized that there are modifying elements, such as immediate demand, nitrification stage demand, sedimentation, and scour, which are highly important in a theoretical scientific analysis; but, in so far as routine technique for the design of remedial works is concerned, until such time as these refinements are firmly established, the writer prefers to include them in the factor of safety used in design.

[6] *Loc. cit.*, p. 298.

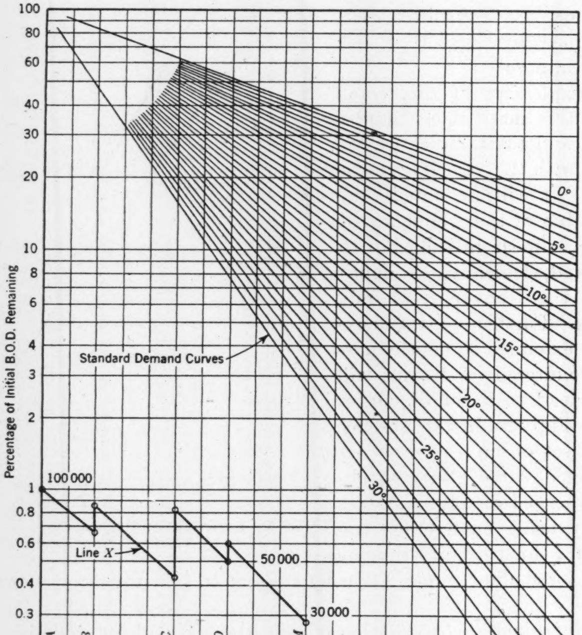

FIG. 6.—RELATIONSHIP BETWEEN BIO-CHEMICAL OXYGEN DEMAND AND TIME AT TEMPERATURES, 0°C TO 30°C

The technical literature of the ten years, 1927–1937, is replete with discussion of the fundamentals of bio-chemical oxidation, but these fundamentals are not so widely used in actual practice. As a stimulus to their further application to practical problems, the writer presents a convenient graphical representation of the well-known time-temperature functions. By plotting the logarithm of oxygen demand expressed as a percentage of the total initial demand against time, for rates at temperatures from 0° C to 30° C, the nest of Standard Demand Curves shown on Fig. 6 is obtained. These curves signify that, at a given temperature in successive intervals of time, the proportion of the demand satisfied is always a constant percentage of that remaining at the end of the previous interval—a very convenient relationship. The influence of temperature upon the rate of oxidation (by coincidence) is similar to that determining the rate of diffusion in reoxygenation; namely, the log of the rate is directly proportional to temperature. With the logarithmic slopes of the standard demand curves known, and with the distance between stations expressed in time of passage, the temperature of the water and the quantities of pollution contributed (expressed in any convenient term such as population equivalents), at each station, known, it is a simple graphical operation to integrate the resultant demand and determine the relative responsibility of polluters at any place in the course of the stream.

Line *X*, Fig. 6, represents such a resultant demand curve for the hypothetical conditions given in Table 1. This technique for integrating resultant demand affords a rapid, direct means of evaluating deoxygenation, which is the "load factor" in the design of projects to remedy pollution problems.

Oxygen Balance

Oxygen balance is the algebraic summation of satisfied demands of pollution and stream assets. A scientific guide in planning measures to correct stream pollution is afforded in a series of oxygen-balance profiles computed for variations in the three major factors: Predicted pollution loads, probable stream flows, and proposed combinations of remedial plans. Evaluation of the relative effect of these factors is essential to safeguard natural resources and to insure the greatest return from remedial works with the least expenditure of funds. For the convenience of the computer the writer has indicated an oxygen balance procedure in Tables 2, 3, and 4.

Variation in pollutional load is a function of population and, except for unusual concentrations of industrial waste, is directly proportional to it. How much to build now, how much excess capitalization to provide for growth, when to add units, or to increase degree of treatment—these questions depend to a large extent upon the prediction of future loads. A well co-ordinated long-range program permits a more conservative allowance for these factors in the basis of design. Restriction of immigration increase in the average age of the population, a declining birth rate, and redistribution of population, are

time in deoxygenation and reoxygenation. Uncontrollable disturbance of equilibrium in Nature's oxygen balance is almost entirely associated with variations in the rate of stream flow. Of run-off so little is known that it is considered a chance phenomenon, and, consequently, it is evaluated by standard statistical methods, a determination of probability of occurrence based upon recorded past behavior. With the possible exception of winter when an ice cover closes the stream to reoxygenation, the coincidence in summer of high temperature and low run-off provides the critical stream condition. For most problems, therefore, an analysis of the summer monthly average run-off records is sufficiently accurate for purposes of design.

A convenient system for establishing the run-off probability curve is afforded by the graphical method developed by the late Allen Hazen, M. Am. Soc. C. E.[7] If a duration flow curve is made of monthly average run-offs, showing the relative frequencies of flows exceeding any given value, a curve of the logarithms of these flow values against percentage frequencies of occurrence plotted on probability paper approaches a straight line. Fig. 7 represents a typical probability curve. From such a curve the most probable minimum flow for any desired percentage chance of occurrence is readily obtained.

[7] "Flood Flows," by Allen Hazen, John Wiley & Sons, Inc., 1930.

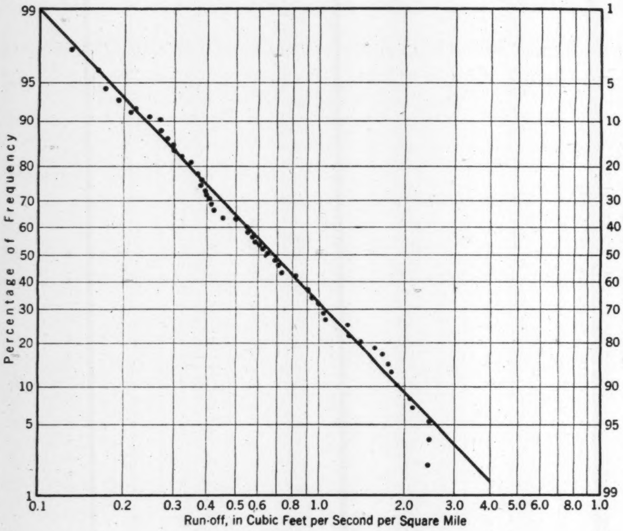

FIG. 7.—RUN-OFF PROBABILITY CURVE

Although any particular oxygen-balance profile is possible of reasonably exact determination from the fundamental laws governing deoxygenation and reoxygenation, load factors and run-off probabilities are not definitely predictable. However, by computing a series of oxygen-balance profiles over a range of loads and run-off, accurate limits of stream condition are defined. Obviously, these defined limits afford a foundation work from which to measure the necessity and effectiveness of any arrangement of treatment plants designed to relieve the stream of portions of the pollution load. The subjection of various remedial combinations to such evaluation insures the proper protection to the stream and to the taxpayer.

DISCUSSION

Earle B. Phelps, Esq.[8] (by letter).—In two ways, this paper is a distinct contribution to the practical art of stream pollution control. By an ingenious development of graphic procedures, Mr. Velz has simplified the application of the complicated formulas of re-aeration and de-aeration and has rendered them directly applicable to any given situation. It is especially important that this simplification has been introduced without altering the form of the basic equations. The latter are rational in form and their constants are capable of experimental determination. Their conversion to simpler empirical forms leads too readily to loss of significance and to faulty applications. This, the author has happily avoided.

Of equal importance is the author's insistence upon the study of stream loadings as a factor in design. If a highway engineer were to build a dirt road and utilize it until traffic became impossible because of stalled cars, and then replace it with a six-lane concrete highway when two lanes would suffice, he would be subject to legitimate criticism; and yet, raw sewage is often discharged in increasing loads until the resulting stream conditions become intolerable. Then treatment is undertaken upon the basis of some successful procedure elsewhere, or under some general specifications of a State authority, and wholly apart from any but the most casual reference to stream capacity.

In his paper entitled "Economics of Sewage Treatment,"[9] George J. Schroepfer, Assoc. M. Am. Soc. C. E., has emphasized the fact that the first point of attack is a determination of the required degree of treatment. Mr. Velz' contribution fits exactly into this vacant niche and, in a sense, "completes the picture." It may quite reasonably be stated, that, in sewage treatment of any kind, the economic determination of the extent of treatment required is at least of correlative importance with the complementary discussion of the economics of design.

Perhaps the first systematic attempt at establishing stream capacities was that made by the late Frederic P. Stearns, Past-President, Am. Soc. C. E., who, in 1890, studied Massachusetts streams carrying varying sewage loadings upon the basis of dilution per contributing capita. He suggested,[10] as tentative limits, that a dilution of less than 2.5 cu ft per sec per 1 000 persons leads to inadmissible pollution and that a corresponding dilution of 7 cu ft leads to results that are clearly inoffensive. The late Allen Hazen, M. Am. Soc. C. E., in his 1898 report on the Ohio River,[11] set the limits of necessary dilution at 1.5 to 4.0 cu ft, noting, however, that in the case of sluggish streams the dilution might have to be increased even to 10 cu ft. In 1902, the late X. H. Goodnough, M. Am. Soc. C. E., on the basis of more extensive Massachusetts data agreed[12] essentially with Mr. Stearns but set the upper safe limit at 6 cu ft, and the lower limit of necessary dilution at 3.5 cu ft. The late Rudolph Hering, M. Am. Soc. C. E., based his Chicago Drainage Canal design upon a dilution ratio of 3.33 cu ft. It will be particularly noticed that throughout all this period only Mr. Hazen made any allowance for the influence of velocity of flow although this influence is traditional. With present-day knowledge, a simple computation will readily show that, in any of these minimum dilution volumes that have been set up, the stream must rely largely upon re-aeration to preserve any semblance of purity.

[11] "Investigation of Rivers," Special Rept., Ohio State Board of Health, 1897.

[12] Rept., Mass. State Board of Health, 1902.

The British Royal Sewerage Commission, in its 8th Report (1912), recognized re-aeration as a factor in stream pollution standards and made an attempt to evaluate it.

The Engineering Board of Review, of the Sanitary District of Chicago (1925), clearly recognized the essential relation existing between dilution and the oxygen demand of sewage but the most recent textbooks either omit all reference to re-aeration as a stream asset or merely note the lack of quantitative knowledge concerning it.

In 1915 the writer made a report to the International Joint Commission in which the principles of permissible loading and of allocation of stream assets among the users of the boundary waters of the Great Lakes system were laid down as bases for a remedial program.[13]

Under the direction of Mr. C. A. Holmquist, Director of the Division of Sanitation, New York State Department of Health, a similar study was made in 1932 of the capacity of the Hudson River below Albany, N. Y. Mr. Velz was associated with the writer in that study. The oxygen profile was determined under summer conditions, and estimates were made of the rate of de-oxygenation and re-aeration, and of the relation of the contribution of each community to the total pollution of the stream. A similar treatment of the pollution and self-purification of New York Harbor, as influenced by the ebb and flow of the tidal prism as well as by the flow of the Hudson, has been published.[14]

In making plain the necessity for such considerations and in developing and presenting a simplified and workable method for their application the author has rendered the profession a distinct service.

Briefly stated, de-aeration is a function of concentration of oxidizable organic matter, temperature, and time. The form of this function, and its time and temperature constants, have been adequately investigated and are comparable in their accuracy and applicability to weir formulas and others of similar nature upon which engineers rely in many of their design problems. Re-aeration is a function of the initial state of de-aeration or saturation deficit, of time and temperature, and of stream turbulence. The basic constants of this relation are also known with sufficient accuracy, except that, for the present, the item of turbulence must be determined in a more or less empirical manner. As shown by H. W. Streeter, M. Am. Soc. C. E., and the writer[15] it may be developed in streams as a somewhat complicated function of depth, velocity, and wetted perimeter. In larger areas of more nearly quiescent water, the late William Murray Black, M. Am. Soc. C. E., and the writer have shown that it may likewise be developed as a function of depth, wind velocity, agitation by passing boats, and the movement of tidal flow through constricted sections.[16] In each case the turbulence factor appears in the basic formula as a time relation expressed in the form "time between mixings." The author's experience, indicating that under many conditions occurring in actual practice on small streams this time may be taken at from $\frac{1}{8}$ hr to $\frac{1}{2}$ hr for streams ranging from shallow, rapid-flowing, to deep slow-flowing, probably represents satisfactory approximations. The British Royal Sewerage Commission, on the basis of direct observations with dye solutions, estimated for some of the larger streams times of mixing ranging from 1 hr in the case of moderately rapid flows to 6 hr in the case of very sluggish flows. The results, computed on this basis, were found to be in practical agreement with those of field investigation and of laboratory experiments in tanks.[17]

[15] "Factors Concerned in the Phenomena of Oxidation and Re-aeration," by H. W. Streeter and Earle B. Phelps, *Public Health Bulletin 146*, Washington, D. C., 1925.

It is believed that the procedures advocated by the author are worthy of much wider use on the part of those charged with the responsibility of stream control and that such use will result in economy of effort and conservation of resources.

C. J. Velz,[18] Assoc. M. Am. Soc. C. E. (by letter).—A technique for the evaluation of stream assets and pollution liabilities, in relation to remedial programs, is essential to a sound and economical solution of the pollution problem. Professor Phelps has drawn an apt parallel with highway construction and has shown that the functions and constants in deoxygenation and reoxygenation are established, and that they are comparable in accuracy and applicability to those used by engineers in other fields. When he is designing for specific loads and conditions, in order to be reasonably certain that the structure will fulfill, safely and economically, the functions intended, the bridge engineer subjects his design to a rigorous analysis. Although the sanitary engineer deals with constantly changing, living, forces rather than inanimate, static, forces, knowledge concerning the rates of change are sufficiently established to permit evaluations similar to those made by the bridge engineer. If sanitary engineering is to be placed on a plane equal to that of other branches of engineering, arbitrary selection in design, based on practical experience alone, must become secondary to a systematic technique of analysis based upon a knowledge of the fundamentals involved.

In discussing the rate of stream turnover, Professor Phelps mentions the work of the British Royal Commission[17] in which it is estimated that the rate of mixing ranges from 1 hr to 6 hr. Analysis of the experimental work of the Stream Pollution Laboratory of the United States Public Health Service and comparisons of computed and observed dissolved oxygen profiles of streams indicate shorter periods—$\frac{1}{8}$ hr to $\frac{1}{2}$ hr. Experimental data that are suitable in the analysis of rates of mix are meager, and it is hoped that further flume studies on reoxygenation, similar to those undertaken by the United States Public Health Service (particularly with greater depths and with more definite control of mix intervals) will bring forth more exact knowledge concerning this factor. Confirmation of the shorter mix period is evidenced from a comparison of computed and observed conditions on the Ohio and the Hudson rivers. H. R. Crohurst[19] has presented rates of reoxygenation, in pounds of oxygen per thousand square feet of water surface per day between sampling stations. They are based upon the assumption that the difference in oxygen balance between April and other months represents reoxygenation that occurred during those months. In a strict sense, such a method of determining rates of reoxygenation is not exact since all discrepancies and errors are "lumped" in the residual oxygen balance and, therefore, are reflected in the rates determined from them. In order to minimize any discrepancies thus included, a stretch of river, and months of the year that show a decided regeneration in dissolved oxygen, were selected by the writer for comparison with rates obtained from the Standard Reoxygenation Curve (Fig. 3).

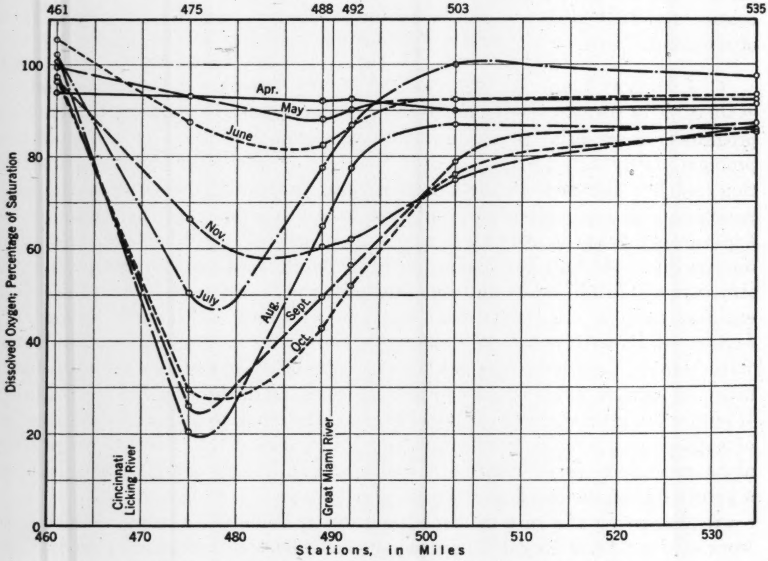

FIG. 8.—DISSOLVED OXYGEN PROFILE; OHIO RIVER, 1930

The dissolved-oxygen profiles of the Ohio River (see Fig. 8) show[19] that, during the months of July, August, September, and October, 1930, the stretch of the river below Cincinnati, Ohio, and between the junctions of the Licking and the Great Miami rivers was subject to a very pronounced regeneration of oxygen content. Utilizing the velocities of flow reported for these months and the corresponding mean rates of stream turnover determined by the author from the experimental data reported by the U. S. Public Health Service,[20] the writer has computed rates of reoxygenation in this stretch of the river by means of the Standard Reoxygenation Curve. These computed values agree closely with the rates based upon observed dissolved oxygen at Stations 475 and 488 as shown in Table 5. Under Item 4, Table 5, the computations are: Pounds per 1 000 sq ft times 4.9, divided by depth of river, in meters, times mean observed oxygen-saturation deficit, expressed as a decimal ratio. The variation in the rates are within the probable errors of observation and under these conditions the experimental rates of mix are identical with the actual rates of turnover in the river; namely, between 5 min and 25 min.

A further verification of the shorter period of stream turnover is indicated by a comparison of the computed and observed dissolved oxygen values on the Hudson River. In these computations the writer used rates of mix ranging from $\frac{1}{8}$ hr for shallow reaches to $\frac{1}{2}$ hr for deep reaches. The agreement between the observed and the computed profiles is shown in Fig. 9.

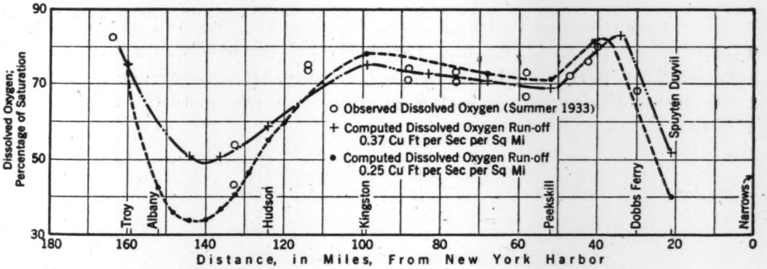

FIG. 9.—DISSOLVED OXYGEN PROFILE, HUDSON RIVER

In addition to verification of the shorter period of stream turnover, the Hudson River data emphasize, strikingly, the importance of the element of depth in reoxygenation.

---

[20] *Sewage Works Journal*, March, 1936.

In the upper reaches from Albany, N. Y., to Hudson, N. Y., the river is relatively shallow and here both observed and computed values of reoxygenation are shown to be pronounced. In passing through this stretch, the river satisfies 90% of a heavy pollution debt and at the same time rebuilds, by reoxygenation, to about 75% of saturation. From Kingston, N. Y., to Peekskill, N. Y., the river passes through a deep gorge section (60 ft to 100 ft); and, with only 10% residual pollution load from up stream, and very small additional pollution loads added in the stretch, reoxygenation through the deep section is unable to satisfy the relatively light demand evidenced by the change from positive to negative slope of the dissolved oxygen profile. Upon entering the shallow reaches of Tappan Zee below Peekskill, reoxygenation is again pronounced, as indicated by a decided increase in computed, and also observed, dissolved oxygen. The sudden drop in oxygen below the Zee is caused by the heavy concentration of pollution from the Metropolitan area.

Quite apart from the verification of the rate of turnover, the important fact to be observed from the Hudson River data is the dominating influence that depth plays in the reoxygenation phenomenon. The only rational approach to computation of reoxygenation which directly employs this important factor of depth is that laid down by Professor Phelps in 1908 in his reoxygenation equation.[3] This formula is the basis for the writer's Standard Reoxygenation Curve (Fig. 3). The importance of depth is frequently obscured by other factors, which has led some workers, particularly Europeans, to express rates of reoxygenation in terms of oxygen absorbed per unit of surface area without designation of specific depth. Such values are applicable only to streams of the same depth; use of these surface rates at other depths may lead to error.

Technique is no substitute for judgment; in the last analysis judgment is the deciding factor in any given situation. It is hoped, however, that the method of analyzing stream assets and pollution liabilities, offered in this paper, will be a useful tool, and will be an aid to sounder judgment in the solution of pollution problems.

The writer wishes to thank Prof. Gordon M. Fair and H. W. Streeter, Members, Am. Soc. C. E., and Prof. Edward W. Moore, for their valuable criticism. In particular he wishes, respectfully, to acknowledge indebtedness to Professor Phelps, whose earlier writings were primarily the foundation for this paper.

PRELIMINARY DESIGN OF SUSPENSION BRIDGES

By Shortridge Hardesty,[1] and Harold E. Wessman,[2]
Members, Am. Soc. C. E.

With Discussion by Messrs. A. W. Fischer, Jacob Karol, Glenn B. Woodruff and Norman C. Raab, Hardy Cross, A. A. Eremin, A. Fraser Rose and William A. Rose, Leon S. Moisseiff, O. H. Ammann, Leon Blog, and Shortridge Hardesty and Harold E. Wessman.

Synopsis

A rapid and accurate method of analysis for the preliminary design of the stiffening trusses of suspension bridges is presented in this paper. The method demonstrates clearly the related functions of the cable and the stiffening truss, emphasizing the fact that the former is the major structural element and that the latter is added to reduce undesirable grade changes. It is useful in determining quickly the effect of variations in the proportions, chord sections, and materials of the stiffening trusses, of differences in loadings, or of changes in major dimensions of the bridge. The proposed method gives results at the center and quarter-points which agree closely with those obtained by the deflection theory. Typical computations for the Triborough Suspension Bridge, at New York, N. Y., accompanied by detailed explanations, illustrate the procedure.

Introduction

Description of Method.—Certain types of statically indeterminate structures are hybrid[3] in their action. Every time a change is made in dimensions or design sections, a change occurs in the moments at various sections of such structures. The stiffening trusses of a suspension bridge act in this manner. Regardless of arbitrary limits imposed upon deflections or grade changes, the designer has a choice of many different stiffening trusses; and in some cases, with large dead load and small live load, he may omit them entirely, as was

[3] "The Relation of Analysis to Structural Design," by Hardy Cross, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1363.

done in the George Washington Bridge over the Hudson River at New York, N. Y. There is a definite need for a rapid method of analysis for preliminary design studies of stiffening trusses, so that the engineer may form some intelligent conclusions as to what happens when he varies the depth or changes the chord sections, selects a new sag ratio, changes the weights of flooring, or moves main towers and anchorages to different relative positions. Heretofore, three methods of analysis have been available, but none of them is satisfactory for making rapid studies of a variety of designs.

The so-called "elastic theory" used in earlier days is obsolete. Its equations are misleading and erroneous. True enough, when the structure is very stiff, the elastic theory gives results which are not much in error; but, as the stiffening truss becomes more and more flexible, the error becomes very large. One need only to point to the George Washington Bridge and ask the question, "How much error would have resulted if this structure had been designed by the elastic theory?"

The "deflection theory" is usually termed the exact method because it accounts for the change in shape of the cable under live load and temperature variations and the resulting changes in moments and shears in the stiffening truss. The term, "exact," is relative, however, because, as ordinarily applied, the method involves assumptions which result in some error. On the other hand, it is much more scientific and accurate than the elastic theory. Unfortunately, the exponential formulas of the deflection theory require long and involved computations. It is necessary to use a computing machine or a table of logarithms in order to avoid possibilities of serious error.

The "trigonometric series" method is the third method of analysis. The equations of this method, which are expressed in terms of trigonometric series that converge very rapidly, also account for changes in the shape of the cable. Although it is not commonly used, the trigonometric series method has distinct advantages over the deflection theory. Non-uniform suspender pull is accounted for in the determination of the horizontal component of the cable stress. What is more important, a slide-rule may be used for practically all computations without sacrificing accuracy. This simplifies procedure and saves time, but the computations are still lengthy and involved. Consequently, like the deflection theory, it is not satisfactory for studies of a variety of preliminary designs, although it is an excellent tool for the analysis of the final design. The trigonometric series method has been extended by the writers to provide a basis for precise computations made to support the derivation of certain formulas developed in this paper; but this treatment is not included.

In the proposed preliminary design method, the maximum moments at the quarter-point and at the center of the main span are computed in two major steps: First, the deflections of an unstiffened cable under partial live load, for various ratios of live load to dead load, are computed on the assumption that the cable length is unchanged and the tower tops do not move. An average value of load length is used, which value was determined from a study of the load lengths giving maximum moments at the quarter-point and at the center of the stiffening trusses of several actual bridges.

The effect of adding the stiffening truss is then considered. Evidently the truss will attempt to conform to the curve of deflection of the cable. It will reduce the deflection, however, and assume some compromise position depending upon its stiffness. The bending moment taken by the truss in its attempt to conform to the deflected cable will be a function of the maximum deflection of the cable at certain points and the truss stiffness. A trial moment of inertia is used, and corrected later if found necessary. A single numerical coefficient accounts for non-uniform suspender loading. The moment is evaluated primarily from the important consideration that, if the cable is kept from assuming its natural position as an unstiffened cable, the stiffening truss must provide the bending moment required to hold the cable in its restrained position.

Finally, the changes in the length of the cable due to live load or to rise and fall of temperature, and the sag changes caused by movement of the tower tops or by the interaction between the side spans and the main span, are combined into one change in the center sag. This lowers or raises the truss, causing a moment which is added algebraically to the moment obtained in the first step.

The changes in center sag of the side span are necessarily found in order to evaluate loading conditions that govern the main span. From these sag changes, it is a simple matter to compute the maximum positive and negative moments at the center of the side span trusses.

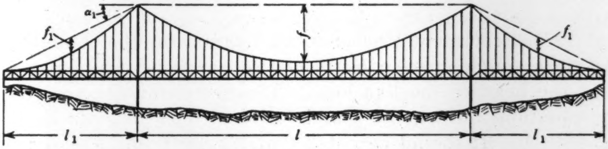

FIG. 1.—SUSPENSION BRIDGE WITH TWO-HINGED STIFFENING TRUSS AND SUSPENDED SIDE SPANS

Fig. 1 is a line diagram of a two-hinged suspension bridge of the type discussed in this paper. The method applies equally well to suspension bridges with straight back-stays.

Notation.—The meanings of the symbols used in this paper are given where they first appear and are assembled, for convenience of reference, in the Appendix.

DEFLECTIONS OF AN UNSTIFFENED CABLE

Cable Ordinates for Dead Load and Mean Temperature.—The cable of a suspension bridge is a flexible member having practically no resistance to bending. Its shape depends upon the initial sag and the loading; in fact, the cable curve is an equilibrium polygon for the loads suspended from it. Consequently, for any condition of loading, the unstiffened cable assumes a curve that represents the moment diagram for the same loading on a simple span. The horizontal component of the cable stress, multiplied by the ordinate at any section, must equal the bending moment at the same section due to the loads on the cable span, considered as a simple beam. With only dead load on the span,

$$H_w\, y = \frac{w}{2}(l\,x - x^2) \quad \text{.....................} \quad (1a)$$

in which w = total dead load per unit horizontal length of cable; H_w = horizontal component of cable stress due to dead load and mean temperature; l = length of main span; and x and y = co-ordinates of any point of cable curve, measured from an origin at the top of the left tower, under dead load at mean temperature. If the center sag is f,

$$H_w = \frac{w\,l^2}{8f} \tag{1b}$$

Substituting Equation (1*b*) in Equation (1*a*):

$$y = \frac{4f}{l^2}(l\,x - x^2) \tag{2}$$

which is the familiar parabolic formula for the cable ordinates under dead load at mean temperature.

The deflections of an unstiffened cable for partial live loads and varying ratios of live load to dead load are first to be found, with cable stretch omitted. Consequently, these deflections are based on an unchanged cable length L, and no relative movement of the tower tops. The equations for the cable ordinates under various live load conditions must first be derived. The differences between the resulting ordinates and those computed from Equation (2) will then give the desired deflections.

Live Load on One End of Span.—When live load moves upon the structure and extends a distance $k\,l$ from the left tower, the cable changes shape. The new curve, which represents the moment diagram for the combined live and dead load on a simple span, consists of two parabolas that have a common tangent at the head of the live load. The new ordinates are given by the following equations, which are simply expanded statements of the law of statics, $\Sigma\,M = 0$. It should be noted that H_w has been increased by a value H_a due to live load. When $x < k\,l$ (that is, for the part of the span under live load), there results the following equation, in which w_l = live load on roadway, per unit length of truss,

$$(H_w + H_a)\,y = \frac{w}{2}(l\,x - x^2) + w_l\,k\,l\left(1 - \frac{k}{2}\right)x - \frac{w_l\,x^2}{2} \tag{3a}$$

or,

$$y = \frac{(w + w_l)\,(l\,x - x^2) - w_l\,l\,(1 - k)^2\,x}{2\,(H_w + H_a)} \tag{3b}$$

When $x > k\,l$ (that is, for that part without live load), there is found:

$$(H_w + H_a)\,y = \frac{w}{2}(l\,x - x^2) + w_l\,k\,l\left(1 - \frac{k}{2}\right)x - w_l\,k\,l\left(x - \frac{k\,l}{2}\right) \tag{4a}$$

or,

$$y = \frac{(w\,x + w_l\,k^2\,l)\,(l - x)}{2\,(H_w + H_a)} \tag{4b}$$

With only dead load on the span, the horizontal component, H_w, of the cable stress is easily determined from Equation (1*b*), which involves the initial center sag, f. When live load moves on to the span, the center sag changes. As a consequence, the determination of the new horizontal component, $H_w + H_a$, is not quite so simple. The quantity $H_w + H_a$ will be determined in this step on the assumption that the cable length l does not change. The effect of changes in cable length will be discussed subsequently. If there is no change in length, the external work performed in deflecting the cable must equal zero; hence,

$$\int_0^{kl}\left(w + \frac{w_l}{2}\right)\eta\,dx + \int_{kl}^{l} w\,\eta\,dx = 0 \ldots\ldots\ldots\ldots (5)$$

in which η = the deflection of truss and cable, at any section, from their initial position under dead load at mean temperature. For values of $x < k\,l$, the deflection, η, equals Equation (3*b*) minus Equation (2); and for values of $x > k\,l$, it equals Equation (4*b*) minus Equation (2). Making these substitutions in Equation (5), performing the integrations, and combining terms, there results:

$$H_w + H_a = \frac{w\,l^2}{8f}\left[\frac{2 + 3\dfrac{w_l}{w}k^2(3 - 2k) + \dfrac{w_l^2}{w^2}k^3(4 - 3k)}{2 + \dfrac{w_l}{w}k^2(3 - 2k)}\right] = \frac{w\,l^2}{8f}C_1 \ldots (6)$$

Substituting Equation (6) in Equations (3*b*) and (4*b*), the following important equations are obtained:

For $x < k\,l$,

$$y = \frac{4f}{l^2}\,\frac{\left(1 + \dfrac{w_l}{w}\right)(l\,x - x^2) - \dfrac{w_l}{w}(1 - k)^2\,l\,x}{C_1} \ldots\ldots\ldots (7a)$$

and, for $x > k\,l$,

$$y = \frac{4f}{l^2}\,\frac{\left(x + \dfrac{w_l}{w}k^2\,l\right)(l - x)}{C_1} \ldots\ldots\ldots\ldots\ldots (7b)$$

in which C_1 is the quantity within the brackets in Equation (6).

Live Load in Middle of Span.—When the live load occupies the middle of the span, symmetrically placed about the center line with a total length of $k\,l$, the cable curve consists of three parabolas with common tangents at the ends of the live load. The two end parabolas are identical. The derivation of the equations is similar to the preceding case and will not be repeated. The final equations are as follows:

$$H_w + H_a = \frac{w\,l^2}{8f}\left[\frac{2 + \dfrac{3\,w_l}{2\,w}(3\,k - k^3) + \dfrac{w_l^2}{w^2}(3\,k^2 - 2\,k^3)}{2 + \dfrac{1\,w_l}{2\,w}(3\,k - k^3)}\right] = \frac{w\,l^2}{8f}C_2 \ldots (8)$$

For the end sections under dead load only,

$$y = \frac{4f}{l^2}\,\frac{(l\,x - x^2) + \dfrac{w_l}{w}k\,l\,x}{C_2} \ldots\ldots\ldots\ldots\ldots (9a)$$

(in which C_2 is the quantity within the brackets in Equation (8)); and for the middle part subject to both live and dead load,

$$y = \frac{4\,f}{l^2}\,\frac{\left(1 + \frac{w_l}{w}\right)(l\,x - x^2) - \frac{w_l}{w}\frac{l^2}{4}(1 - k)^2}{C_2} \ldots\ldots\ldots\ldots (9b)$$

Live Load on Both Ends of Span.—When live load is placed on both ends, covering a length $k\,l$ at each end, the new cable curve consists of three parabolas, the two end ones again being identical. The final equations are:

$$H_w + H_a = \frac{w\,l^2}{8\,f}\left[\frac{2 + 3\,\frac{w_l}{w}(6\,k^2 - 4\,k^3) + 8\,\frac{w_l}{w^2}\,k^3}{2 + \frac{w_l}{w}(6\,k^2 - 4\,k^3)}\right] = \frac{w\,l^2}{8\,f}\,C_3 \ldots (10)$$

For the end parts, subject to both live and dead load,

$$y = \frac{4\,f}{l^2}\,\frac{(l\,x - x^2) + \frac{w_l}{w}(2\,k\,l\,x - x^2)}{C_3} \ldots\ldots\ldots\ldots (11a)$$

in which C_3 is the quantity within the brackets in Equation (10). For the middle part under dead load only,

$$y = \frac{4\,f}{l^2}\,\frac{(l\,x - x^2) + \frac{w_l}{w}\,k^2\,l^2}{C_3} \ldots\ldots\ldots\ldots (11b)$$

Application of Equations (1) to (11).—Equations (1) to (11) are employed only in computing the basic deflections, and need not be used in applying the approximate method. They are stated in order to demonstrate how the proposed method has been developed.

It will be noted, by examining the governing equations for cable ordinates, that the span of the cable has no effect whatever upon the deflections. When x in the numerator is considered as a proportional part of l, it is evident that the term l^2 in the denominator is cancelled. The deflections of the cable depend only upon the initial sag f, the ratio of live load to dead load $\frac{w_l}{w}$, and the load length factor k. Now k can be made a constant in securing maximum effects at definite points in a span, such as the quarter-point or the center point, regardless of the span length. Hence, curves of deflection for the cable may be plotted for different ratios of live load to dead load, but with a constant proportional load length, $k\,l$. The deflections may be expressed as percentages of the initial sag, f. Then, if the deflection of a cable is wanted for a definite $\frac{w_l}{w}$ ratio, one needs only to select the percentage of deflection corresponding to the proper ratio and multiply the value by the cable sag.

An investigation of various load lengths, $k\,l$, indicated that changes in the $\frac{w_l}{w}$ ratio had practically no effect on the loaded length that would produce maximum deflections at the quarter-point and at the center of the span

Moreover, it was found that the load lengths which produced maximum downward and upward deflections were about the same as those which caused maximum positive and negative moments in the stiffening trusses. The following values of $k\,l$ were found to be accurate enough for preliminary design purposes:

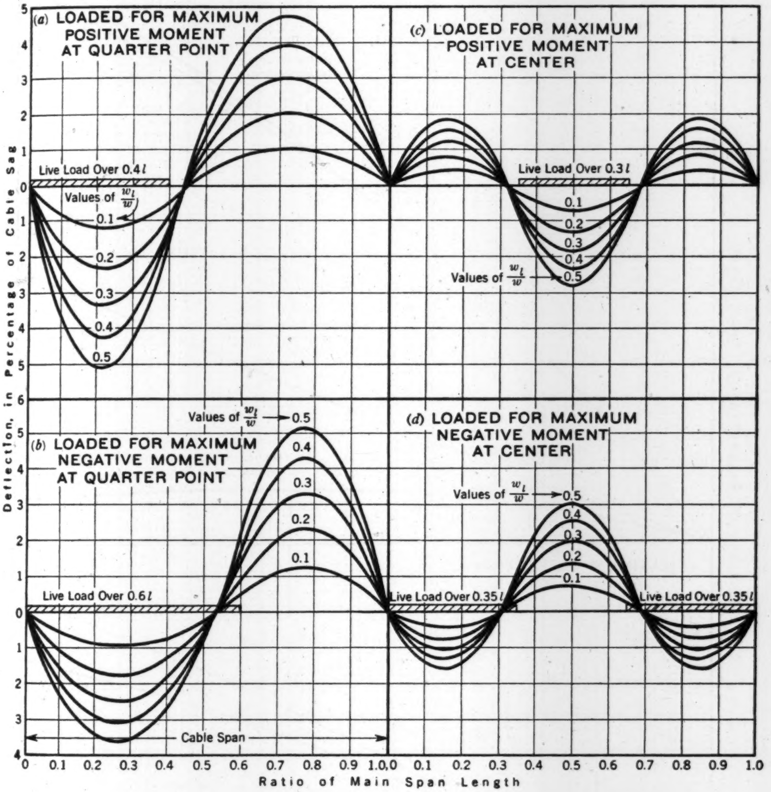

FIG. 2.—DEFLECTIONS OF UNSTIFFENED CABLE DUE TO PARTIAL LIVE LOADS PRODUCING MAXIMUM MOMENTS AT QUARTER-POINT AND AT CENTER. DEAD LOAD OVER ENTIRE SPAN

Condition	Load length
Maximum positive moment at the quarter-point,	0.4 l at the same end of span
Maximum negative moment at the quarter-point,	0.6 l at far end of span
Maximum positive moment at the center.......	0.3 l at center of span
Maximum negative moment at the center.......	0.35 l at both ends of span

These load lengths were used to compute the deflections of the unstiffened cable for ratios of live load to dead load ranging from 0.1 to 1.0. Some of the

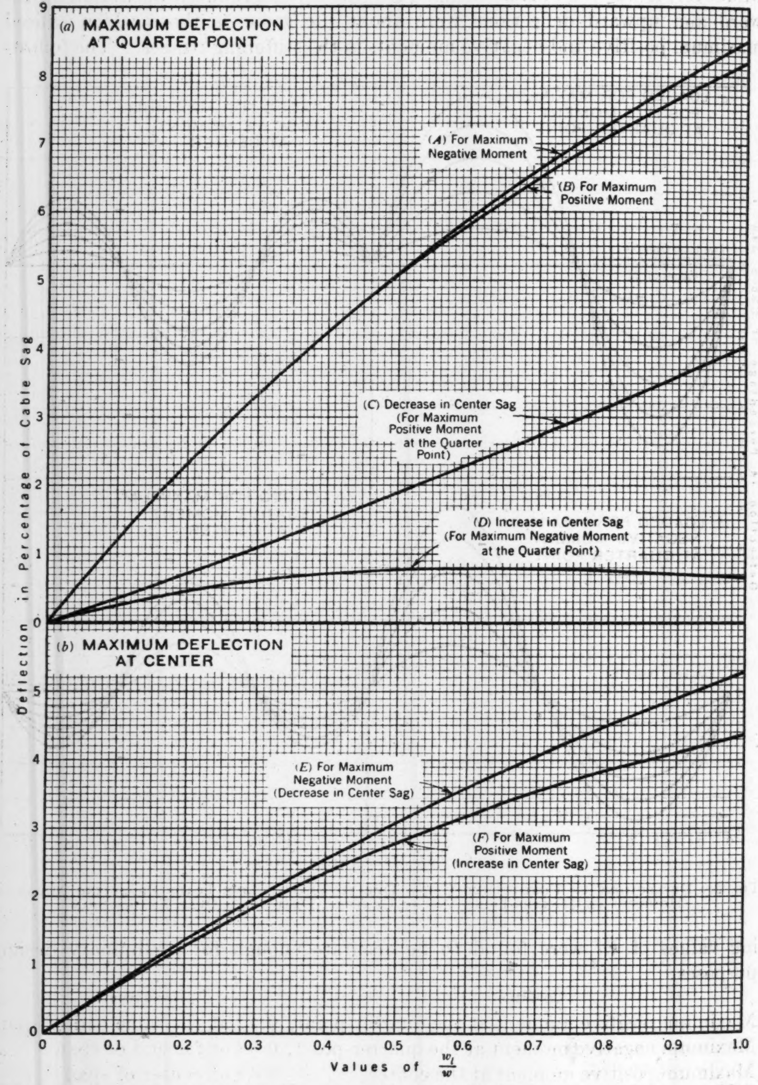

FIG. 3.—MAXIMUM DEFLECTIONS OF UNSTIFFENED CABLE AT QUARTER-POINT AND CENTER OF MAIN SPAN DUE TO PARTIAL LIVE LOADS

curves showing the procedure at the quarter-point and the center are drawn in Fig. 2. The maximum downward deflections in Fig. 2(*a*) were then plotted against the $\frac{w_l}{w}$ ratio, as Curve *B* in Fig. 3(*a*). This curve obviates interpolation for intermediate $\frac{w_l}{w}$ ratios. The decreases in center sag corresponding to the loading giving maximum positive moment at the quarter-point are also plotted in Fig. 3(*a*) (see Curve *C*). The other curves were obtained in a similar manner.[4]

Figs. 3(*a*) and 3(*b*) are the only curves used in applying the proposed method.

EFFECT OF ADDING STIFFENING TRUSS TO UNSTIFFENED CABLE

Bending Moment, M, in Stiffening Truss.—When a stiffening truss is attached to the cable and the live load is moved on to the span, the cable tends to force the stiffening truss to conform to the deflection curve of the unstiffened cable. If the truss were very flexible, it would practically conform to that curve; whereas, if it were infinitely stiff, it would not deflect at all, and the cable would be forced to remain in its original position. Since the cable offers resistance to anything tending to force it back to its initial position, and since the truss is neither very flexible nor infinitely stiff, the final position of truss and cable will evidently be a compromise between the original dead load position of the cable and the deflection curve of the unstiffened cable, as indicated in Fig. 4(*a*).

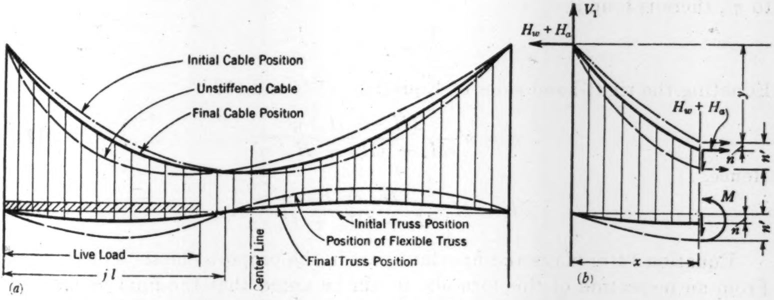

FIG. 4.—DEFLECTION OF CABLE AND STIFFENING TRUSS UNDER PARTIAL LIVE LOAD

In reaching this compromise position, the laws of statics will necessarily be satisfied (note Section *x* in Fig. 4(*b*)). The external bending moment due to dead load at mean temperature is balanced by $H_w\, y$. When live load comes upon the roadway, there is an additional external moment acting at Section *x*. If there were no stiffening truss, or if the truss were so flexible that it could resist no moment, the cable would deflect through a distance η'; and the total external moment would be balanced by $(H_w + H_a)\, y + (H_w + H_a)\, \eta'$. If, on the other hand, the truss had infinite stiffness, the cable deflection would be reduced from η' to 0; in other words, the truss would force the cable back through the entire distance η' to its original dead load position. The change η' in the lever arm of the force, $H_w + H_a$, would upset the balance of moments at Section x, in so far as the cable is concerned; and this balance would be restored by the stiffening truss taking a moment equal to $(H_w + H_a)\,\eta'$, in order to satisfy the equation of statics, $\Sigma\, M = 0$.

---

[4] The extensive computations for these curves are not included in the paper, but have been filed for reference in Engineering Societies Library, 33 West 39th Street, New York, N. Y.

Since the truss is neither infinitely flexible nor infinitely stiff, the cable will be forced back only a part of the distance η'. Let the final deflection, shown in Fig. 4(*b*), be η. The change in lever arm is then $\eta' - \eta$; and the moment resisted by the stiffening truss is,

$$M = (H_w + H_a)\,(\eta' - \eta) \quad \text{(12)}$$

From one point of view, this moment resisted or developed by the stiffening truss may be considered as moment taken away from the cable when its position is changed from that of an unstiffened cable. This statement is not intended to convey the idea that the cable itself resists bending moment. The cable is flexible, but the force in the cable, multiplied by a lever arm, most certainly constitutes a moment at a section of the structure.

The deflection η of Equation (12) is found in the following manner. Let M_t be the bending moment at Section x that would be induced in the stiffening truss if it were bent to the deflection η' of the unstiffened cable. Its value will be determined later in terms of the deflection η', the physical properties of the truss, and a loading which accounts for variation in suspender pull. Assuming the final stiffening truss moment, M, to bear the same ratio to M_t as η does to η', there is found:

$$M = M_t \frac{\eta}{\eta'} \quad \text{(13)}$$

Equating the right-hand sides of Equations (12) and (13):

$$\eta = \eta' \frac{(H_w + H_a)\,\eta'}{M_t + (H_w + H_a)\,\eta'} \quad \text{(14a)}$$

Hence,

$$M = M_t \frac{(H_w + H_a)\,\eta'}{M_t + (H_w + H_a)\,\eta'} \quad \text{(14b)}$$

Equation 14(*b*) plays an important part in the proposed method of analysis. From an inspection of this formula, it will be noted that the final moment M in the stiffening truss is less than the moment $(H_w + H_a)\,\eta'$ that would be induced by forcing the cable back to its original position. One may consider either that the ratio $\frac{(H_w + H_a)\,\eta'}{M_t + (H_w + H_a)\,\eta'}$ determines the proportion of the moment M_t taken by the truss, or that the ratio $\frac{M_t}{M_t + (H_w + H_a)\,\eta'}$ represents the proportion of the moment $(H_w + H_a)\,\eta'$ taken by it. The latter ratio shows also the proportion of the deflection η' that is eliminated by the stiffening truss in this step of the process.

Horizontal Component of Cable Stress.—By an inspection of the terms of Equation 14(*b*), it will be noted that the deflection η' is determined from

Fig. 3(*a*) and Fig. 3(*b*), which leaves two other quantities, M_t and $(H_w + H_a)$, to be evaluated. The latter quantity is the horizontal component of the cable stress due only to dead load and live load on the unstiffened cable. This horizontal component is found by computing the moment M_c' of the dead load and live load at the center of the span, just as if the span were a simple beam, and then dividing by the center sag. In equation form:

$$H_w + H_a = \frac{M_c'}{(f + \eta_c')} \dots\dots\dots\dots\dots\dots (15a)$$

in which $(f + \eta_c')$ = the center sag, and η_c' = increase or decrease in the center sag taken from the curves of Fig. 3(*a*) and Fig. 3(*b*). With only the dead load, w, acting:

$$H_w = \frac{w\,l^2}{8f} = 0.125\,\frac{w\,l^2}{f} \dots\dots\dots\dots\dots\dots (15b)$$

Evidently, in this case, f is the center sag of the cable in its original position. When live load comes on, however, the center ordinate f changes by an amount η_c'. It should be kept in mind that the effect of cable stretch and temperature is to be considered subsequently. For the time being, deflections which are caused by partial live load are used, with the length of the cable l kept constant.

For the cases of loading summarized in Fig. 2(*c*) and Fig. 2(*d*), the values of $H_w + H_a$ are as follows:

Maximum positive moment at the quarter-point, with live load at the same end, over a length of 0.4 l,

$$H_w + H_a = \frac{1}{f + \eta_c'}\,(0.125\,w\,l^2 + 0.040\,w_l\,l^2) \dots\dots (16a)$$

Maximum negative moment at the quarter-point, with live load at the opposite end over a length of 0.6 l,

$$H_w + H_a = \frac{1}{f + \eta_c'}\,(0.125\,w\,l^2 + 0.085\,w_l\,l^2) \dots\dots (16b)$$

Maximum positive moment at the center, with live load at the center over a length of 0.3 l,

$$H_w + H_a = \frac{1}{f + \eta_c'}\,(0.125\,w\,l^2 + 0.0638\,w_l\,l^2) \dots\dots (16c)$$

Maximum negative moment at the center, with live load over a length of 0.35 l at each end,

$$H_w + H_a = \frac{1}{f + \eta_c'}\,(0.125\,w\,l^2 + 0.0613\,w_l\,l^2) \dots\dots (16d)$$

In each of the preceding equations, the quantity within the parenthesis is the bending moment at the center of a simple span due to dead load over the entire span and live load over a part of the span. The deflection η_c' is positive when downward and negative when upward.

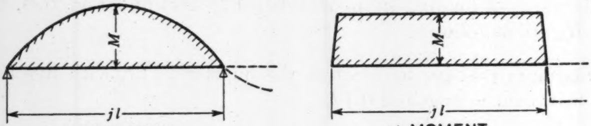
The horizontal component of cable stress may be found in a similar manner for other conditions of loading. Equations (16) are sufficient, however, for preliminary design purposes.

Bending Moment, M_t, in Stiffening Truss.—The bending moment M_t in Equation (14*b*), denoting the moment that would be induced in the stiffening truss if it were bent to the deflection curve of the unstiffened cable, will now be evaluated. For convenience, consider the case of maximum positive moment at the quarter-point. Deflection curves for this case are plotted in Fig. 2(*a*) and Fig. 2(*b*). The stiffening truss will be bent into the two loops shown, one downward and one upward. This is also indicated in Fig. 4. If η' is the maximum deflection of the downward loop and $j\,l$ is the length of the base of the loop, the bending moment may be stated thus, in general terms:

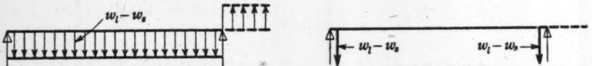
$$M_t = C\,\frac{E\,I\,\eta'}{(j\,l)^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (17)$$

in which C is a numerical coefficient depending upon the shape of the moment diagram; or, in other words, the type of loading on the truss. The loading involves both the live load on the roadway and the live load suspender pulls.

It will be well to consider approximate moment diagrams first, in order to show the relationship between M_t and η'.



(*a*) MOMENT (*c*) MOMENT



(*b*) LOADING (*d*) LOADING

FIG. 5.—APPROXIMATE MOMENT AND LOAD DIAGRAMS

If the moment diagram on one loop of the truss is a parabola, as shown in Fig. 5(*a*), the deflection at the center of the loop is,

$$\eta' = \frac{5}{48}\,\frac{M_t\,(j\,l)^2}{E\,I} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (18a)$$

and, the maximum moment is,

$$M_t = 9.6\,\frac{E\,I\,\eta'}{(j\,l)^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (18b)$$

The loading creating such a parabolic moment diagram is uniform over the length, $j\,l$, and is designated as $w_l - w_s$ in Fig. 5(*b*). The deflection curve would evidently be a fourth degree curve in this case.

Next suppose that the moment diagram is almost rectangular, as in Fig. 5(*c*), rather than parabolic. Then the center deflection would be,

$$\eta' = \frac{1}{8}\,\frac{M_t\,(j\,l)^2}{E\,I} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (19a)$$

and the maximum moment would be,

$$M_t = 8.0 \frac{E\,I\,\eta'}{(j\,l)^2} \dots\dots\dots\dots\dots\dots\dots\dots (19b)$$

The loading creating such a moment diagram would consist of two equal concentrated loads near the ends of the span, as in Fig. 5(*d*), or two equal end couples. The deflection curve in this case would be a second degree curve or a parabola.

The loadings in the two cases shown are radically different, but the maximum moments, M_t, for the same deflection differ by about 17%; and the final M-values, determined from Equation (14*b*) for these two values of M_t, would differ from one another by less than 8% in most cases.

The actual loading diagram for each loop of the stiffening truss falls somewhere between the two cases shown in Fig. 5. In an approximate method, one might assume arbitrarily that the suspender loading is uniform; but the final moments computed by the deflection theory are not determined from a uniform suspender pull, even if that assumption is used in finding the value of H_a. Hence, to make the proposed preliminary method as accurate as possible, actual moment and load patterns for partial live loads should be studied. Some mathematical relations must first be established to facilitate such a study.

Relationship Between Suspender Pull and Truss Moment.—The initial curve of the cable under dead load and mean temperature is,

$$y = \frac{4\,f\,x}{l^2}(l - x) = \frac{w\,x}{2\,H_w}(l - x) \dots\dots\dots\dots\dots (20a)$$

The familiar differential equation of this curve is,

$$H_w \frac{d^2y}{dx^2} = -\,w \dots\dots\dots\dots\dots\dots\dots\dots (20b)$$

When an additional load, w_s, due to live load or temperature change, acts through the suspenders upon the cable, the cable ordinates become $y + \eta$, and the differential equation becomes,

$$(H_a + H_w)\frac{d^2(y + \eta)}{dx^2} = -\,(w + w_s) \dots\dots\dots\dots (21a)$$

that is,

$$-\frac{H_a}{H_w}w - w + (H_a + H_w)\frac{d^2\eta}{dx^2} = -\,(w + w_s) \dots\dots\dots (21b)$$

or,

$$w_s = \beta\,w - (H_a + H_w)\frac{d^2\eta}{dx^2} \dots\dots\dots\dots\dots\dots (21c)$$

in which β is the ratio $\frac{H_a}{H_w}$. Equation (21*c*) gives the value of the suspender pull w_s.

The differential equation of curvature for the stiffening truss is,

$$\frac{d^2\eta}{dx^2} = -\frac{M}{E\,I} \dots\dots\dots\dots\dots\dots\dots\dots (22)$$

The curvature of the stiffening truss is the same as that of the curve of deflection of the cable. The value in Equation (22) when substituted in Equation (21c) gives the following important relationship:

$$w_s - \beta\, w = \frac{H_a + H_w}{E\,I}\, M \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

Since $\frac{H_a + H_w}{E\,I}$ is a constant for one loading condition, the final bending-moment diagram on the truss must have the same shape as the diagram of live load pull, w_s, on the suspenders, minus a constant proportion of the dead load pull, w. The diagram may be determined quantitatively from Equation (23), but the major significance of this is qualitative. It is evident that a parabolic moment diagram such as that in Fig. 5(a) and a load diagram such as that in Fig. 5(b) are not possible.

(e) FINAL TRUSS LOADING, $w_t = w_l + w_s$

FIG. 6.—MOMENT AND LOAD DIAGRAMS FOR STIFFENING TRUSS

For a live load extending over a length of 0.4 l, the moment diagram on the truss, with no stretch effects included, is a curve of two loops, approximately like that in Fig. 6(a). The (w_s − β w) diagram must be similar, as in Fig. 6(b). Adding β w to this curve, the hanger-pull diagram in Fig. 6(c), for live load only, is the result. Combining Fig. 6(c) with the live load w_l on the roadway (Fig. 6(d)) gives the final load diagram, Fig. 6(e), for the truss. This is the loading that is associated with the shears and bending moments in the stiffening truss. It should be kept in mind that the dead load, w, has no effect on the stiffening truss at mean temperature, and is not considered, therefore, as a load on the truss. Even if $k\,l$ should be somewhat less than $j\,l$, it is evident that the loading for each loop falls somewhere between the two cases shown in Fig. 5. Consequently, the coefficient C in Equation (17) must lie between 9.6 and 8.0. To verify this, several deflection, moment, and load diagrams, computed precisely by the trigonometric series method, have been studied, omitting the effects of cable stretch due to live load and temperature change, and the effect of side-span interaction. These studies have been presented in detail elsewhere.[5]

---

[5] "Related Functions of Cable and Stiffening Truss in Suspension Bridges," by Harold E. Wessman, Assoc. M. Am. Soc. C. E.; Thesis presented to the Univ. of Illinois in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

As a result of these studies and comparisons of results obtained by the preliminary design method with final values for a number of bridges computed by the deflection theory, the following values of the coefficient C, to be used in Equation (17), have been adopted for the preliminary design method:

Maximum positive or negative moment at:	Value of C
Quarter-point	9.1
Center	9.0

Specific Values of M_t.—Definite values of $j\,l$ for Equation (17) have been determined by using the average lengths of the bases of the deflection loops of the unstiffened cable. For positive moment at the quarter-point, $j\,l = 0.44\,l$. For negative moment at the same point, $j\,l = 0.46\,l$. For positive moment at the center, $j\,l = 0.37\,l$, and for negative moment at the center, $j\,l = 0.39\,l$. When these values and the preceding values of C are inserted in Equation (17), the following specific values of M_t are obtained:

Maximum positive moment at quarter-point:

$$M_t = 9.1\,\frac{E\,I\,\eta'}{(0.44\,l)^2} = 47.0\,\frac{E\,I\,\eta'}{l^2} \quad \ldots\ldots\ldots\ldots\ldots (24a)$$

Maximum negative moment at quarter-point:

$$M_t = 9.1\,\frac{E\,I\,\eta'}{(0.46\,l)^2} = 43.0\,\frac{E\,I\,\eta'}{l^2} \quad \ldots\ldots\ldots\ldots\ldots (24b)$$

Maximum positive moment at center:

$$M_t = 9.0\,\frac{E\,I\,\eta'}{(0.37\,l)^2} = 65.8\,\frac{E\,I\,\eta'}{l^2} \quad \ldots\ldots\ldots\ldots\ldots (24c)$$

Maximum negative moment at center:

$$M_t = 9.0\,\frac{E\,I\,\eta'}{(0.39\,l)^2} = 59.2\,\frac{E\,I\,\eta'}{l^2} \quad \ldots\ldots\ldots\ldots\ldots (24d)$$

Equations (24) are based upon a constant length, $j\,l$, regardless of the stiffness of the truss attached to the cable. In other words, they imply that the points of zero deflection for partial live loads (with cable stretch and side-span effects omitted) remain practically fixed in position. An inspection of the deflection loops in Fig. 2(*a*) and Fig. 2(*b*) indicates that the points of zero deflection do not move much for different ratios of live load to dead load. Consideration was also given to the possible effect of stiffness of truss upon the point of zero deflection, as it was thought that a very stiff truss might possibly cause the point to travel appreciably toward the unloaded end of the truss. To test this hypothesis, the main truss of the Manhattan Suspension Bridge, in New York, N. Y., was replaced by a truss ten times as stiff, and the deflections were then computed for a live load from 0 to $0.4\,l$, with cable stretch and side-span effects omitted. It was found that the point of zero deflection remained practically fixed in position. This check, combined with a number of comparisons of values obtained in actual designs, gave assurance relative to the use of the preliminary design method for a wide range in truss stiffness.

All the values for use in Equation (14*b*) are now established; η' is determined from Fig. 3(*a*) and Fig. 3(*b*); values of $H_w + H_a$ are found from Equations (16); and values of M_t are computed by using Equations (24). This completes the first and major step of the approximate method. It is now necessary to evaluate the effects of cable stretch, temperature change, and side-span interaction.

EFFECT OF CABLE STRETCH, TEMPERATURE CHANGE, AND SIDE-SPAN INTERACTION

Introduction.—When live load moves upon the bridge, or when a temperature change occurs, stress is induced in the cable. This stress causes a change in the normal length of the cable; that is, the length corresponding to full dead load and mean temperature. When a temperature change takes place, the cable lengthens or shortens a distance which is in addition to any length change produced by the stress from live load or temperature change. These changes affect the shape of the cable, increasing or decreasing the center sag and producing positive or negative bending moments in the stiffening truss.

Any change in cable stress or length of the cable also causes a change in the side-span sag. This, in turn, causes a movement of the tower tops which, finally, affects the center-span sag. A change in center sag is accompanied by a change in the cable stress, which will again modify the side-span sag. Evidently, there is an interaction between the side span and the main span, which occurs simultaneously with any change in loading or temperature. When the bending moments in the stiffening truss due to changes in cable length and side-span interaction have been found, the results are to be added algebraically to the moments from live load found by Equation (14*b*).

Change in Length of Cable Due to Stress.—The strain in any section of the cable of differential length, due to stress from live load or temperature, is:

$$\delta = \frac{H_a\, dL}{A\, E_c\, dx}\, dL \qquad (25)$$

The total strain or change in length of the main-span cable may then be expressed as follows:

$$\Delta L_s = \int_0^l \frac{H_a}{A\, E_c} \frac{dL^2}{dx} \qquad (26)$$

When evaluated, this gives the following approximate equation to be used for the main span in the preliminary design method:

$$\Delta L_s = \frac{H_a\, L}{A\, E_c\, l} L = \frac{H_a\, L^2}{A\, E_c\, l} \qquad (27)$$

This simplified equation was used by Allston Dana, M. Am. Soc. C. E., and G. M. Rapp, Assoc. M. Am. Soc. C. E., in the cable calculations for the Delaware River Bridge, from Philadelphia, Pa., to Camden, N. J.[6] It should be noted that l is the horizontal length of the main span and L is the actual length of the cable; L is given quite accurately by Equation (28), as follows:

---

[6] "The Delaware River Bridge Connecting Philadelphia, Pa., and Camden, N. J.," Final Rept. of the Board of Engrs., p. 107.

$$L = l\,(1 + \frac{8}{3}n^2) \quad \text{......(28)}$$

in which n = ratio $\frac{f}{l}$. (D. B. Steinman, M. Am. Soc. C. E., has published[7] a comparison of exact and approximate formulas for cable length.) Likewise, the change in length of the cable over each side span may be expressed as,

$$\Delta L_{1s} = \frac{H_a\,L_1^2}{A\,E_c\,l_1} \quad \text{......(29a)}$$

in which l_1 is the horizontal length of the side span, and L_1 is the actual length of the side-span cable, or (see Fig. 1):

$$L_1 = l_1\left(\sec\alpha_1 + \frac{8}{3}\,\frac{n_1^2}{\sec^3\alpha_1}\right) \quad \text{......(29b)}$$

There are other short sections of the cable over the tower saddles and at the anchorages, which also change length and contribute to the effects upon the stiffening truss. For one-half the bridge, these sections will be designated by the length term, L'. Then,

$$\Delta L_s' = \frac{H_a\,(L')^2}{A\,E_c\,l'} \quad \text{......(30)}$$

in which l' is the horizontal length of the section of cable corresponding to L'. At the tower saddle, l' is virtually equal to L'.

Change in Length of Cable Due to Temperature.—The change in length of the cable over the main span due to temperature variation is,

$$\Delta L_t = \omega\,\Delta t\,L \quad \text{......(31a)}$$

The corresponding change over the side span is,

$$\Delta L_{1t} = \omega\,\Delta t\,L_1 \quad \text{......(31b)}$$

The change in length of other sections of length, L', for one-half the bridge is,

$$\Delta L_t' = \omega\,\Delta t\,L' \quad \text{......(31c)}$$

It should be noted that the changes of length indicated by Equations (27), (29), (30), and (31) are separated into units corresponding to the main span, the side span, and incidental sections of the cable. This separation is convenient in order to evaluate the changes in cable sag due to cable strains.

Relations Between Cable Strain, Cable Sag, and Span Length.—Any change in the length of the cable is accompanied either by a change in the sag or by a change in the horizontal span length. The relation between a small change in sag and a small change in the length of cable, with the span length kept constant, is expressed approximately as follows:[8]

---

[7] "Suspension Bridges," by D. B. Steinman, p. 6.

$$df = \frac{15}{16\,n\,(5 - 24\,n^2)}\,dL \qquad \text{(32a)}$$

The relation between a small change in sag and a small change in span length with the cable length kept constant is:

$$df = -\frac{(15 - 40\,n^2 + 288\,n^4)}{16\,n\,(5 - 24\,n^2)}\,dl \qquad \text{(32b)}$$

The relation between a small change in span length and a small change in cable length, with the sag kept constant, is:

$$dl = \frac{15}{(15 - 40\,n^2 + 288\,n^4)}\,dL \qquad \text{(32c)}$$

Equations (32) apply to the main span, and, corresponding equations may be developed for the side span. Usually, the side-span sag ratio is so small that the terms involving n_1^2 and n_1^4 may be omitted without sacrificing reasonable accuracy in a preliminary design method. Then Equations (32) take the following form for the side span:

$$df_1 = \frac{3}{16\,n_1}\sec^3\alpha_1\,dL_1 \qquad \text{(33a)}$$

$$df_1 = -\frac{3}{16\,n_1}\sec^2\alpha_1\,dl_1 \qquad \text{(33b)}$$

and,

$$dl_1 = dL_1\sec\alpha_1 \qquad \text{(33c)}$$

To find the change in the cable sag at the center of the main span due to cable stretch in the main span from stress, or due to change in length of the cable caused by temperature, the values of ΔL_s or ΔL_t from Equations (27) or (31*a*) are substituted for dL in Equation (32*a*); but changes of length, ΔL_1, of the cable in the side spans cause the tower tops to move, thus changing the horizontal length, l, of the main span by a length, dl. The horizontal movement of each tower top is approximately equal to $\Delta L_1 \sec \alpha_1$. If the side spans are symmetrical, the total change is as follows:

$$dl = -2\,\Delta L_1\sec\alpha_1 \qquad \text{(34)}$$

Any change in length of the part of the cable from the end of the side span to the anchorage must be included in ΔL_1 in Equation (34). Moreover, the change in length of the short section of the cable over the tower saddles causes the tower tops to move horizontally a distance equal to the change in length. This is doubled to account for the other side span and then added to the increment, dl, in Equation (34). When all the horizontal movements of the tower top have been combined, the differential change in sag, df, is found from Equation (32*b*).

---

[8] "Modern Framed Structures," by Johnson, Bryan, and Turneaure, Pt. II, Ninth Edition, p. 199.

Effect of a Change in Sag Upon the Main-Span Stiffening Truss.—Whenever the center sag of the main-span cable changes by an amount, df, the stiffening truss is raised or lowered by the same amount at the center. Forces are transmitted to the truss through the suspenders or hangers. If the hanger forces are uniformly distributed, the moment in the truss at the center will be:

$$M = 9.6 \frac{E\,I}{l^2}\,df \qquad (35)$$

Moments at other points would vary as the ordinates of a parabola. The hanger forces are not uniformly distributed, however. An inspection of the $(w_s - \beta\, w)$ diagram, which must look like the moment diagram, will verify this. An investigation of exact load diagrams indicated that the stiffening truss is subject to a non-uniform hanger load of greatest intensity at the ends and decreasing toward the middle. The moment diagrams are slightly elliptic in shape rather than parabolic. Consequently, the following equations are proposed in the preliminary design method for the computation of the center moment in the stiffening trusses caused by changes in sag:

For the main span at the center,

$$M = 9.4 \frac{E\,I}{l^2}\,df \qquad (36a)$$

and, for the side span at the center,

$$M = 9.4 \frac{E\,I_1}{l_1^2}\,df_1 \qquad (36b)$$

For exact results, the value of M given by Equation (36*a*) should be adjusted, such adjustment being carried out by means of equations analogous to Equations (14*a*) and (14*b*); but the correction would be small, and not worth while.

The moment diagrams, as already indicated, are elliptic in shape. For a parabola, the moment ordinate at the quarter-point would be 0.75 of the center ordinate. For a true ellipse, the ordinate at the quarter-point is 0.866 of the center ordinate. A study of calculated moment diagrams for cable-stretch effects indicates that the quarter-point moment should be approximately 0.81 of the center moment for preliminary design purposes. Hence, the following equations are proposed for the computation of the moments at the quarter-points caused by changes in center sag:

For main span at the quarter-point,

$$M = 0.81 \times 9.4 \frac{E\,I}{l^2}\,df = 7.6 \frac{E\,I}{l^2}\,df \qquad (37a)$$

and, for the side span at the quarter-point,

$$M = 7.6 \frac{E\,I_1}{l_1^2}\,df_1 \qquad (37b)$$

Side-Span Interaction.—When the side spans of a suspension bridge are suspended from the cable, the side-span sag, f_1, is made such a value that the horizontal component of the cable stress under dead load and mean temperature has the same value for both the side span and the main span; then:

$$H_w = \frac{w\,l^2}{8f} = \frac{w_1\,l_1^2}{8\,f_1} \qquad (38a)$$

or,

$$f_1 = \frac{w_1\,l_1^2}{w\,l^2} f \qquad (38b)$$

What happens to the side-span sag when live load is placed on the main span, or when there is a change in temperature? First, consider the case with no stiffening truss in the side span. The horizontal component of cable stress has increased to the value $H_w + H_a$. If the tower saddle is free to move, or if the tower has very little resistance to horizontal forces at the top, the sag, f_1, in the side span must decrease by an amount df_1, in order to preserve equilibrium; then:

$$H_w + H_a = \frac{w_1\,l_1^2}{8\,(f_1 + df_1)} \qquad (39a)$$

or,

$$(H_w + H_a)\,(f_1 + df_1) = \frac{w_1\,l_1^2}{8} = H_w\,f_1$$

and,

$$df_1 = -\frac{H_a}{H_a + H_w} f_1 \qquad (39b)$$

In Equation (39*b*) the minus sign indicates a decrease in sag for positive values of H_a. When a stiffening truss is added to the side span, a decrease, df_1, in side-span sag creates negative bending moments in the stiffening truss, as indicated in Equations (36*b*) and (37*b*). At the center of the span, the equation of statics, $\Sigma\,M = 0$, is satisfied when,

$$(H_w + H_a)\,(f_1 + df_1) + 9.4\,\frac{E\,I_1}{l_1^2}\,df_1 = \frac{w_1\,l_1^2}{8} = H_w\,f_1 \qquad (40a)$$

and,

$$df_1 = -\frac{H_a}{(H_w + H_a) + 9.4\,\dfrac{E\,I_1}{l_1^2}} f_1 \qquad (40b)$$

Due to the stiffening truss, the change in sag in Equation (40*b*) has a smaller value than the change in sag given by Equation (39*b*). If there is a uniform live load, w_{1l}, over the side span, in addition to the dead load, the equation of equilibrium becomes,

$$(H_w + H_a)\,(f_1 + df_1) + 9.4\,\frac{E\,I_1}{l_1^2}\,df_1 = \frac{w_1\,l_1^2}{8} + \frac{w_{1l}\,l_1^2}{8} \qquad (41)$$

but, since $\frac{w_1 l_1^2}{8} = H_w f_1$, and $\frac{w_{1l} l_1^2}{8} = \frac{w_{1l}}{w_1} H_w f_1$, Equation (41) becomes:

$$df_1 = \frac{- H_a + \frac{w_{1l}}{w_1} H_w}{(H_w + H_a) + 9.4 \frac{E I_1}{l_1^2}} f_1 \dots\dots\dots\dots\dots (42)$$

It is often convenient to find cable-stretch effects and sag changes in terms of H_a = 1 000 000 lb, or H_a = 100 000 lb, and then compute the effects for the final value of H_a by direct proportion. This is accurate enough when H_a is small relative to H_w. A trial value of H_a based on Equations (16) is first used. Sag changes are then computed for temperature effect and cable stretch from stress, using this trial value of H_a. From the new sag, a new value of H_a is determined, and the process is repeated until the trial H_a and the final H_a agree, or differ by a very small amount.

The total change in the sag f at the center of the main span due to temperature, cable stretch, and side-span interaction is then consistent with the final value of H_a. From the total sag change, df, the moments in the stiffening truss at the quarter-point and at the center are found from Equations (36*a*) and (37*a*). These moments are added algebraically to the live load moments found from Equation (14*b*), in order to find the final values at the quarter-point and the center to be used in the preliminary design of the stiffening truss.

Since the sag change, df_1, in the side span must be found in order to compute maximum positive or negative moments in the main span, and since the side span is either unloaded or fully loaded with live load to find these main-span moments, it requires little additional computation to find the maximum positive and negative moments at the center of the side span for preliminary design purposes. The value of df_1, when found, is inserted in Equation (36*b*), and the moment is then evaluated.

COMPUTATIONS ILLUSTRATING THE PRELIMINARY DESIGN METHOD

Triborough Suspension Bridge.—A definite structure, the Triborough Suspension Bridge, has been used to demonstrate the typical preliminary design computations rather than some fictitious span, in order that the results obtained by the preliminary analysis may be compared with final values for an actual design.

The procedure outlined in Table 2 will be exactly the same as that for the investigation of an entirely new layout, except for the choice of the moments of inertia of stiffening trusses. Preliminary design data and constants are given in Table 1(*a*), Column (2). In the following computations (Tables 1 and 2) final design values for the moments of inertia of the stiffening trusses are used. In a new layout, it is advisable to use an arbitrarily selected moment of inertia, based on a tentative chord section and truss depth, for the initial determination of maximum moments and deflections. Then the procedure should be repeated with other values of moments of inertia, say, one-half as much and two times as much as those used in the first analysis. By doing this, a fairly accurate idea is obtained of the manner in which maximum bending moments vary with truss stiffness. Moreover, a good measure of the reduction in the deflections of an unstiffened cable, caused by each trial truss, is afforded by this process.

Maximum positive and negative moments at the quarter-point and center of the main span, and at the center of the side span, are computed. Considerable space is devoted to the explanations accompanying each step of the method; as a result, the computations may seem to be more extensive than they actually are. Ordinarily, the numerical computations, which are slide-rule results, require very little space and relatively little time when compared

TABLE 1.—COMPARISON OF DESIGN CHARACTERISTICS OF SUSPENSION BRIDGES

Description (1)	Triborough Bridge, at New York, N. Y. (2)	San Francisco-Oakland Bay Bridge, in California (3)	Manhattan Bridge, at New York, N. Y. (4)	Maumee River Bridge (5)	Mount Hope Bridge, in Rhode Island (6)	Moline-Bettendorf Bridge, at Moline, Ill. (7)

This was determined from a study of precise deflections due to cable stretching. [k] See Step 11(*g*). [m] In Equation (42) use a trial value of $H_a = 2\,250\,000$ lb from Step 3, Table 1(*c*), because this formula is not a linear function of H_a. [n] Steps 10(*f*), 10(*g*), 10(*h*), 10(*i*), and 10(*j*). [o] The side span under consideration is fully loaded with live load; the main spans and the other side span are not loaded; and the value, Δt, is + 55° F. [p] The span under consideration is not loaded; the remainder of the bridge is fully loaded; and the value of Δt is − 55° F.

to the procedure necessary in using the deflection theory or the trigonometric series method. A study of the computations emphasizes the importance of Fig. 3(*a*) and Fig. 3(*b*).

Preliminary Design Values for Other Suspension Bridges.—Maximum moments and corresponding deflections have been computed by the preliminary design method for five additional suspension bridges, ranging from a relatively short and light span to a long and heavy span. Detail computations are omitted from the paper; but the constants for each bridge are given in full in Table 1(*a*). The final results are tabulated in Table 1(*b*), together with the corresponding moments computed by the deflection theory.

Effect of Variation in Truss Stiffness.—In preliminary design studies of suspension bridges, it is important to know approximately what happens to moments and deflections when the truss stiffness is varied. The results in Table 1(*b*) for the San Francisco-Oakland Bay Suspension Bridge are based upon the equivalent uniform moments of inertia of the main span and side-span trusses as actually designed. If an unstiffened cable had been used, the downward deflection at the quarter-point would have been approximately 14.2 ft. Consequently, the truss as designed has reduced the deflection of the cable at the quarter-point from about 14.2 ft to about 10.1 ft.

If the moments of inertia of the main-span and side-span trusses are doubled, the moments become larger and the deflections decrease. If the moments of inertia are decreased, the moments decrease, but the deflections become greater. Fig. 7 shows theoretical values plotted for moments of inertia, I_t, four times, twice, one-half, and one-quarter as much as the moment of inertia I_a used in the actual design. The curves are not exact; nevertheless they give the designer a fairly accurate picture of what happens.

Fig. 7(*a*) indicates that the most economical stiffening truss is no stiffening truss whatever; but Fig. 7(*b*) indicates that the deflections of an unstiffened cable may be too great, and that, therefore, a stiffening truss may be needed. The maximum grade change is probably of more importance than the maximum deflection; even so, Fig. 7(*b*) gives a clue as to what may be expected with trusses of different stiffness, since the deflections and grade changes will vary in about the same ratio. What constitutes the limiting grade change, however, is still a subject for research. Present tendencies are to make stiffening trusses more flexible. Studies like those embodied in Fig. 7 may then be of great help in selecting a proper design. As stated[9] by Hardy Cross, M. Am. Soc. C. E.: "Where the action is hybrid there are many possible structures; the designer must make his choice." The problem becomes one of intelligent selection.

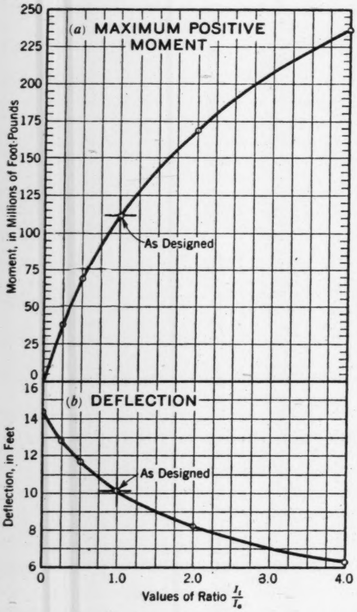

FIG. 7.—EFFECTS AT QUARTER-POINT OF MAIN SPAN OF SAN FRANCISCO-OAKLAND BAY BRIDGE DUE TO CHANGES IN TRUSS STIFFNESS

CONCLUSION

A rapid and accurate method of analysis for the preliminary design of suspension bridges is presented in this paper. The method begins logically with an unstiffened cable and then shows what happens when a stiffening truss is added. The effects of cable stretch from stress and from temperature, and the effect of side-span interaction, are obtained separately, thus giving the designer a good idea of the contributions of the various factors to the final moment and deflection in the stiffening truss. The method demonstrates clearly the related functions of cable and stiffening trusses in suspension bridges.

The method emphasizes the fact that there is no single design for a stiffening truss. There are any number, depending upon what limits are established for deflection and change of grade. The method will also prove a valuable aid in making additional studies which are needed to "throw light" upon suspension bridge design. These studies are indicated in the following questions: When may the stiffening truss be omitted? What is the maximum permissible grade change? Is it more economical to obtain stiffness by increasing the chord section or by increasing the depth of the truss? May one count on the floor system to help the stiffening truss in reducing cable deflections? If so, how must the floor system be connected to insure participation? Will participation "hurt" the floor system more than it will "help" the truss? When should one use alloy steels with higher working stresses than those for ordinary structural steel? Is there a place for alloys with different moduli of elasticity? What are the economics of using light-weight floors?

ACKNOWLEDGMENTS

The writers greatly appreciate the valuable suggestions made during the course of this study by Professor Cross. They also acknowledge the generous co-operation of the following engineers, who supplied final design data for various suspension bridges: Allston Dana, Leon S. Moisseiff, D. B. Steinman, Montgomery B. Case, and C. E. Paine, Members, Am. Soc. C. E., and Ralph A. Tudor, Assoc. M. Am. Soc. C. E.

APPENDIX

NOTATION

The following symbols, introduced where they first appear in the paper, conform essentially with "Symbols for Mechanics, Structural Engineering, and Testing Materials" compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1932:[10]

A = area; cross-sectional area of cable;
C = constants;
E = modulus of elasticity of the stiffening truss and towers; E_c = modulus of elasticity of the cable;
f = sag of cable at the center of the main span; f_1 = sag of cable at the center of the side span;
H = horizontal component of force; H_w = component of cable stress due to dead load and mean temperature; H_a = additional component due to any change from the condition of dead load at mean temperature;
I = moment of inertia of the stiffening truss of the main span; I_1 = moment of inertia of the stiffening truss of the side span;
k = a ratio defining loaded length of stiffening truss;
L = length of cable in main span; L_1 = length of cable in side span;
l = horizontal length of main span; l_1 = horizontal length of side span;
M = moment; actual bending moment in the stiffening truss; M_t = bending moment induced in the stiffening truss if it were bent to the deflection η' of the unstiffened cable; M' = bending moment in the stiffening truss, assuming it to be a simply supported beam;
t = temperature; Δt = temperature change, or variation;

---

[10] A. S. A.—Z10a—1932.

V = actual shear in stiffening truss at any section; V' = shear at any section in the stiffening truss, assuming it be a simply supported beam;

w = total dead load per unit horizontal length of cable; w_l = live load on the roadway per unit length of truss; w_s = suspender pull expressed as a load per unit of horizontal length of cable due to live load or temperature, or both; w_t = final load acting on truss per unit length.

x = co-ordinate horizontal distance of any point of the cable curve, measured from an origin at the top of the left tower, under dead load at mean temperature;

y = co-ordinate vertical distance corresponding to x;

α = slope of the straight line joining the tower tops; α_1 = slope of the chord of the side-span cable;

β = a ratio, $\frac{H_a}{H_w}$;

δ = unit elongation; strain;

η = deflection of truss and main cable, at any section, from its initial position, under dead load at mean temperature; η' = corresponding deflection of unstiffened main cable; and

ω = coefficient of thermal expansion.

DISCUSSION

A. W. Fischer,[11] Esq. (by letter).—In their "Introduction" the authors state that the so-called "elastic theory" used in earlier days is obsolete. The writer thinks, however, that for short spans of, say, 750 ft, or less, the "elastic theory" can be used. (Generally, for spans of 750 ft and less, other types of bridges are more economical.) Referring to the "deflection theory," the authors state that it is quite long and that a computing machine or a table of logarithms must be used in order to avoid possibilities of serious error. The writer agrees that the deflection theory is rather long and he would not use it, for that reason especially, for calculating the value of H_a. After H_a is known, however, the equations for moment and shear given by the "deflection theory," derived by using hyperbolic functions, are as short as any of the exact methods.

The authors state that the "trigonometric series" is not satisfactory for studies of a variety of preliminary designs. The writer much prefers the trigonometric series for the solution of H_a because a slide-rule can be used which gives results that are accurate enough for practical purposes. If the effect of the change of curvature is neglected, then the value of H_a can be calculated in a very short time, and the results will be amply accurate for preliminary design.

The authors then advance their method as being more rapid than the deflection theory or the trigonometric series method. After studying the proposed new method the writer is not convinced that any time is saved by it. It is true that the moments at the quarter-points and the center points of the main span and the moment at the center of the side span agree remarkably with the deflection theory, but even so the method requires considerable computation. The writer did not check the moment of 113 300 ft-kips as given for the quarter-point by the authors' preliminary design for the Manhattan Bridge, but it seems that the results are somewhat too small. By solving for H_a, using the trigonometric series,[12] with the live load covering 0.425 of the main span, neglecting the effect of the change of curvature, and assuming that the ratio of H_a to H_w is 0.2, the writer obtains an answer of 2 028 kips for H_a, and substituting this in an equation involving hyperbolic functions,[13] the value of the moment at the quarter-point is + 118 870 ft-kips. If the effect of the change of curvature is considered, $H_a = 2\,040$ kips and the moment at the quarter-point is + 118 650 ft-kips.

For the Manhattan Bridge, by solving for H_a, using the trigonometric series with the live load covering 0.3 to 0.7 of the main span, considering the effect of the change of curvature, and assuming that the ratio, H_a to H_w, is 0.3, the writer finds 3 166 kips for H_a; and substituting this value in an equation involving hyperbolic functions the value of the moment at the center of the main span is + 88 300 ft-kips. In their preliminary design the authors give 91 300 ft-kips.

In their entire paper the authors do not mention how they propose to compute shear, and for a preliminary design it is also important that the shear is known. The value of H_a can also be readily solved by the trigonometric series, and then substituting in a general equation containing hyperbolic functions,[14] the value of shear can be ascertained.

[12] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 387.

[13] *Loc. cit.*, Vol. 100 (1935), p. 1199, Equation (80); see, also, p. 1200.

For a preliminary design for moment at the quarter-points and the center of the main span, etc., it also seems to the writer that such a method as given by Arvid H. Baker, Assoc. M. Am. Soc. C. E.,[15] is considerably shorter than the authors' method, and the results are such that, for a preliminary design, they are satisfactory. The moment is first solved by reading coefficients from a chart introduced by D. B. Steinman, M. Am. Soc. C. E.,[16] and then applying a correction factor derived by Mr. Baker.[15]

Throughout the entire paper, the writer fails to grasp the meaning of just what is meant by "preliminary design of stiffening trusses of suspension bridges." If it means a preliminary design for estimating purposes, it seems to the writer that too much time will be required when compared with the chart presented in 1926 by the late J. A. L. Waddell, Hon. M. Am. Soc. C. E.,[17] from which the steel in the stiffening trusses must be read by an experienced engineer familiar with suspension bridge designs. Any one who knows the cost of steel in place can make a very close estimate in a short time, and for that reason the writer really sees no particular need for a preliminary design such as that given in the paper.

In their closing discussion the authors should show just how they propose to apply their method to the computation of shear in the main span and in the side spans and, furthermore, they should present a general method for calculating the moments at points other than the quarter-points and center.

Jacob Karol,[18] Esq. (by letter).—The principal merit of this valuable paper lies in the "picture" it presents of the related action of the cable and the stiffening truss. The writer wishes to discuss this pictorial aspect in greater detail.

It has been emphasized, in the literature on the deflection theory of suspension bridges, that stresses for a combined loading cannot be found by a summation of the stresses due to the component loads. Although this statement is strictly true, it is also true, and much more important, to state that superposition of component effects under certain conditions gives a result that is approximately correct.

The authors' method of calculation permits a direct determination of these component effects. In Professor Wessman's original thesis[5] the effect due to the addition of the stiffening truss to the unstiffened cable was designated as Step I, and the combined effect of cable stretch, temperature change, and side-

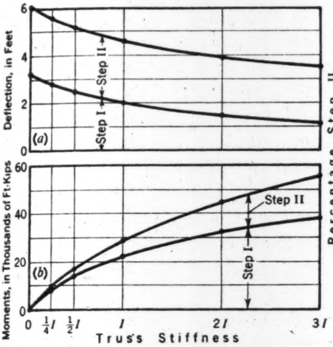

FIG. 8.—EFFECTS AT QUARTER-POINT OF MAIN SPAN OF TRIBOROUGH BRIDGE DUE TO CHANGES IN TRUSS STIFFNESS (LOADING CONDITION, DEAD LOAD + LIVE LOAD + 55° CHANGE OF TEMPERATURE)

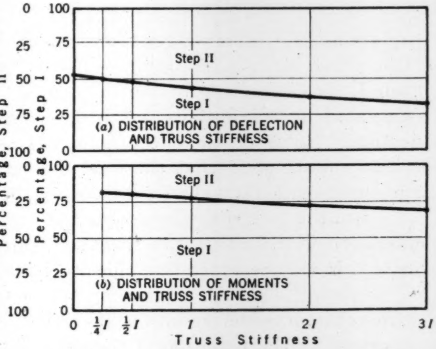

FIG. 9.—EFFECTS AT QUARTER-POINT OF MAIN SPAN OF TRIBOROUGH BRIDGE DUE TO CHANGES IN TRUSS STIFFNESS (LOADING CONDITION, DEAD LOAD + LIVE LOAD + 55° TEMPERATURE)

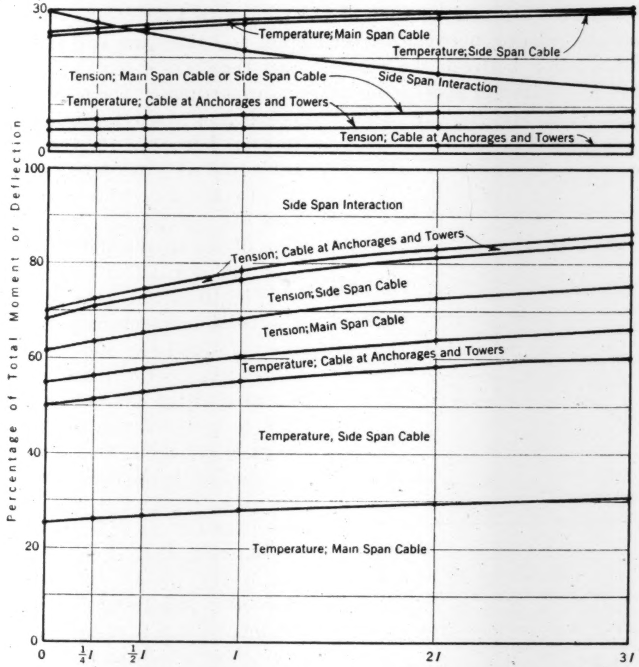

FIG. 10.—EFFECTS AT QUARTER-POINT OF MAIN SPAN OF TRIBOROUGH BRIDGE ON MOMENTS AND DEFLECTIONS FROM CABLE SAG, DUE TO CHANGES IN TRUSS STIFFNESS (LOADING CONDITION, DEAD LOAD + LIVE LOAD + 55° TEMPERATURE)

span interaction was designated as Step II. It may be noted, in passing, that Equation (14*b*), which gives the moment due to Step I, is based on Equation (13), which is an assumption. The writer found that the moment due to Step I, as calculated by the deflection theory, was slightly less than that calculated by the authors' method, whereas the reverse was true of the deflection. However, the effect of Step II as computed by the authors' method is compensating, so that the final moment and deflection are in substantial agreement with the values obtained by the deflection theory.

From the preceding discussion it is obvious that the separation of the total moment and deflection into their component effects is quantitatively approximate. It may be added that this procedure is applicable to the main span only.

Economical design implies an understanding of the relations among the various factors entering into the design. Hence, only by studying the changes produced by the variation of the several factors can one obtain the necessary understanding.

Consider, as an illustration, the positive moment and deflection at the quarter-point of the main span of the Triborough Suspension Bridge, in New York, N. Y., as affected by a variation in truss stiffness, with the ratio of the main span truss stiffness to that of the side span held constant. Fig. 8(*a*) indicates the relation between the deflection and the truss stiffness, and Fig. 8(*b*), the relation between the moment and the truss stiffness. These same data may be plotted in another manner as proportions of the total moment or deflection. Fig. 9(*a*) indicates that the proportion of the total deflection due to Step I is 53% for the unstiffened cable and 31% for a truss stiffness of 3 *I* (*I* is the truss stiffness as designed), and Fig. 9(*b*) shows that the proportion of the total moment due to Step I is 82% for 0.25 *I* and 68% for 3 *I*.

Fig. 10 indicates the proportions of the total moment or deflection from Step II, due to its component factors, in relation to the truss stiffness. It shows that the effects of cable stretch due to temperature and tension are sensibly constant, and that side-span interaction causes 30% of the total for an unstiffened cable and 14% of the total for a truss stiffness of 3 *I*. By considering both Figs. 9 and 10, it seems that about 50% of the total deflection and about 20% of the total moment is due to the unvarying cable stretch effects of Step II.

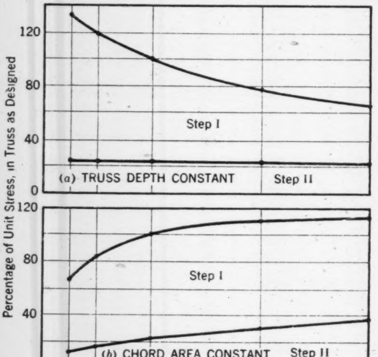

FIG. 11.—EFFECTS AT QUARTER-POINTS OF MAIN SPAN OF TRIBOROUGH BRIDGE ON UNIT STRESSES IN STIFFENING TRUSS DUE TO CHANGES IN TRUSS STIFFNESS (LOADING CONDITION, DEAD LOAD + LIVE LOAD + 55° TEMPERATURE)

Another interesting study is the effect of the truss proportions on the stresses in the chords. Assuming that the truss as designed has a stress of 100%, the preceding data were plotted in Fig. 11. For a constant truss depth, Fig. 11(*a*) indicates that the stress due to Step II is approximately constant, whereas that from Step I decreases with an increase in I. Fig. 11(*b*) shows that for a constant chord area the stresses due to Step I and Step II both increase with an increase in I. Hence, if a structure has been designed with a truss of stiffness, I, depth, d, and chord area, A, the following relations obtain:

Decreasing the value of I, with depth, d, constant, increases the unit stress.
Increasing the value of I, with depth, d, constant, decreases the unit stress.
Decreasing the value of I, with Chord A constant, decreases the unit stress.
Increasing the value of I, with Chord A constant, increases the unit stress.

If it is desired to maintain a constant unit stress, the required relationships can be determined as follows: For the designed truss, let I represent the stiffness; M, the moment; A, the chord area; d, the depth; and s, the unit stress. For a truss of stiffness, $I_n = n\,I$, the corresponding terms are denoted with a subscript, n. Letting $I = \frac{A\,d^2}{2}$,

$$s = \frac{\frac{M\,d}{2}}{\frac{2\,A\,d^2}{2}} = \frac{M}{A\,d} \qquad (43)$$

Similarly,

$$s_n = \frac{M_n}{A_n\,d_n} \qquad (44)$$

From Equations (43) and (44),

$$\frac{M}{A\,d} = \frac{M_n}{A_n\,d_n} \qquad (45)$$

Also, by definition:

$$A\,d^2 = \frac{1}{n}\,A_n\,d_n^2 \qquad (46)$$

From Equations (45) and (46),

$$\frac{A_n}{A} = n\left(\frac{d}{d_n}\right)^2 = \frac{M_n}{M} \times \frac{d}{d_n} \qquad (47)$$

or,

$$\frac{d_n}{d} = n\,\frac{M}{M_n} \qquad (48)$$

and,

$$\frac{A_n}{A} = \frac{1}{n}\left(\frac{M_n}{M}\right)^2 \qquad (49)$$

Applying Equations (48) and (49) to the preceding data gives the results indicated in Fig. 12.

The writer made some further studies to determine the effect of the side-span stiffness on the positive moment and deflection at the quarter-point of the main span, the stiffness of the latter being kept constant and equal to the design value. Fig. 13 indicates a reduction of about 4% in the moment and 10% in the deflection for the extreme variation in side-span stiffness from 0 to 3 I_1.

This, and other, studies by the writer seem to indicate that for a given cable and span layout, the moments and deflections in any span are primarily a function of the stiffness of that span. This statement does not apply unreservedly to the case of continuous stiffening trusses. It should be evident from the foregoing that the authors' method of analysis is of undoubted value in giving a clear and simple picture of the action of a suspension bridge with hinged stiffening trusses. This picture is admittedly approximate quantitatively, but not so approximate as to be misleading. The writer has extended the authors' method to include the determination of the maximum shears in the stiffening trusses. From 80% to 90% of the total shear is due to Step I.

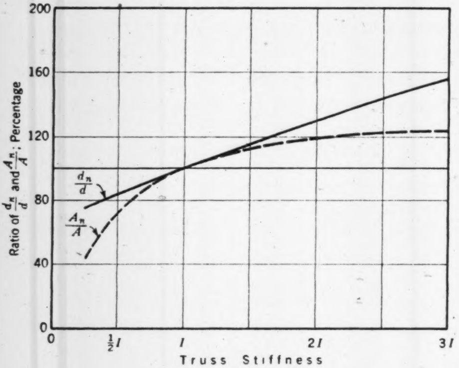

FIG. 12.—EFFECT AT QUARTER-POINT OF MAIN SPAN OF TRIBOROUGH BRIDGE; REQUIRED VARIATION IN TRUSS DEPTH AND CHORD AREA FOR CONSTANT UNIT STRESS WITH VARYING TRUSS STIFFNESS

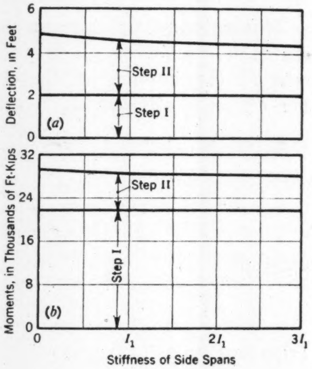

FIG. 13.—TRIBOROUGH BRIDGE; MAXIMUM EFFECTS AT QUARTER-POINT OF MAIN SPAN FOR DESIGN STIFFNESS I IN MAIN SPAN AND VARIOUS VALUES OF I IN SIDE SPANS

In closing, the writer wishes to take exception to the authors' criticism of the deflection theory on the ground that it requires long and involved computations. He has developed an influence line procedure for the generalized deflection theory whereby slide-rule computations are accurate enough for all practical purposes.

Acknowledgment.—These studies of suspension bridges were made under the direction first of Hardy Cross, and, later, of T. C. Shedd, Members, Am. Soc. C. E., as part of the writer's graduate study, and their helpful comments are hereby acknowledged.

GLENN B. WOODRUFF[19] AND NORMAN C. RAAB,[20] MEMBERS, AM. SOC. C. E. (by letter).—Even to the experienced designer, the deflection theory for suspension bridges has heretofore been largely a matter of following formulas without a complete conception of their meanings. The authors are to be congratulated upon their success in presenting a clear picture of the interaction of the various parts of the suspension system. The paper is so complete and the results so convincing that, within its scope, there remains but little to be said. In their "Conclusion," the authors have emphasized several subjects for further investigation. The following is submitted, not as an answer to these problems, but rather as a suggested basis for these investigations.

---

[19] Engr. of Design, San Francisco-Oakland Bay Bridge, San Francisco, Calif.

[20] Senior Designing Engr., San Francisco-Oakland Bay Bridge, San Francisco, Calif.

Before commenting on these problems, reference is made to Fig. 7 which, it is believed, neglects the fact that unless other changes in design are made, changing the truss stiffness would also affect the dead load, which, in turn, would affect the deflections. Assuming that the designers of the San Francisco-Oakland Bay Bridge considered an increase in rigidity necessary, the question arises as to the most economical means of securing such increase. For the present, only the methods of increasing the dead load of the suspended structure, increasing the moment of inertia of the stiffening trusses, or a combination of the two, are considered. To keep the dead load of the structure as low as practicable, light-weight aggregates were used for the 6-in. upper-deck paving slab, at an increased cost for the light-weight as compared to standard aggregates. The cost of the paving, as well as its supporting floor steel, could have been reduced by using standard aggregate. Still further savings in the floor construction could have been made by using a 9-in. paving slab with standard aggregate.

Assuming that the quarter-point deflection is a satisfactory index of rigidity, calculations have been made for the following cases: (I) Original design; (II) 50% increased I (no increase in dead load); (III) 50% increased I (additional weight of trusses and cables included); (IV) changing pavement slab to standard concrete (no increase in I); (V) changing paving slab to standard concrete (30% increased I); and (VI) changing paving slab to 9-in. standard concrete (no increase in I).

TABLE 3.—EFFECT OF MOMENT OF INERTIA ON RIGIDITY

Case	Dead load, in pounds per linear foot of cable	Area of cable, in square inches	Quarter-point moment, in foot-kips	Deflection, in feet	Decrease in deflection	Cost change	Cost per foot, decrease
I	9 200	500	110 000	10.10	....	....	....
II	9 200	500	142 500	8.92	1.18	....	....
III	10 000	530	137 600	8.52	1.58	$1 150 000	$730 000
IV	9 800	525	107 900	9.68	0.42	294 000	700 000
V	10 200	540	124 900	8.94	1.16	976 000	840 000
VI	11 100	570	100 000	9.03	1.07	978 000	910 000

The results for these cases, shown in Table 3, indicate that, for this particular structure, increasing the moment of inertia of the stiffening trusses is, in general, the most economical means of increasing rigidity. They do indicate, however, that there would be no economy in extra expenditures for an extremely light-weight floor and adding truss metal to regain the rigidity lost by decreasing the dead load.

Certain of the additional studies proposed by the authors lead to a specification for the design of stiffening trusses which, in the present stage of suspension-bridge design, is desirable. For this purpose, it is necessary to specify the intensity and distribution of live load, a measure of the required rigidity of the stiffening truss, and the permissible unit stresses. Considering only vehicular loadings, the probabilities of several of the loading conditions assumed in the calculations of maximum stresses in stiffening trusses are so remote that they may be safely discounted to a large extent. The most probable loading, for a bridge subjected to heavy traffic, is to have the roadway filled with passenger cars interspersed with comparatively few trucks and buses. With traffic having an unusually high percentage of trucks and buses, and assuming that the roadway is completely filled, bumper to bumper, the results per 100 vehicles would be approximately as follows:

80 passenger cars	@ 3 200 lb	= 256 000 lb	@ 16 ft	= 1 280 ft
5 buses	@ 16 000 lb	= 80 000 lb	@ 26 ft	= 130 ft
15 trucks	@ 20 000 lb	= 300 000 lb	@ 26 ft	= 390 ft
100 vehicles	@ 6 360 lb	= 636 000 lb	@ 18 ft	= 1 800 ft

With traffic moving slowly, the average space between cars would be about 12 ft, or a total of 30 ft per vehicle. With traffic at a standstill, a load of 35 lb per sq ft is possible. With traffic moving at slow speed, this reduces to 25 lb per sq ft.

It is recognized that traffic is not distributed uniformly and that there may be a sequence of heavy trucks. The probability of such a sequence on one part of the bridge with no loading on the other parts is small, but should be considered a possibility. The probability of such a critical (as used in stiffening truss analysis) loading on more than one lane is more remote. Unless deliberate efforts are made to achieve such a result, the writers do not believe there is any chance of a loading heavier than that of an H-20 truck in the lane adjacent to the stiffening truss and 250 lb per lin ft in the other lanes. As applied to customary practice, the foregoing rule would have the effect of increasing the design loads for two-lane bridges and decreasing those for wider bridges. For the Triborough Bridge, it would produce a live load of 1 500 lb per ft of truss in comparison with the 2 000-lb design load.

In the writers' opinion, the question of omitting the stiffening truss (see "Conclusion") should be reframed to read, "How flexible may the stiffening trusses safely be made?" A certain degree of vertical stiffening is always desirable to spread concentrations over several hangers; otherwise, severe distortion may occur at the stringer connections and at the cable bands. The case of a damaged hanger should be considered. Chords are always required for the wind truss and, as a minimum, the material required therefore should be disposed so as to afford as much vertical stiffening as practicable. Vertical stiffness is also desirable to dampen the vertical waves induced by wind gusts.

A suggestion toward a specification for the degree of vertical stiffening has been made by Sterling Johnston, M. Am. Soc. C. E.[21] The writers, however, suggest that the angular change at any panel or suspender point, rather than the change of grade, be considered the criterion for the required stiffness of the system. Further data are required as to the effects of angular changes on the cable.

---

[21] *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 1210.

If a definite specification based on rigidity is established, there will be so many variables in any specific case (such as economical panel arrangement, back-stay conditions, dead loads, etc.), that each structure will be a separate study and no definite rules as to economic truss depths will cover the large range of possibilities.

The writers believe that efforts should be made to reduce the participation of the floor system in stiffening truss action as much as practicable. Usually, it is not economical to combine direct and bending stresses in any member. In most designs, floor expansion joints are introduced to reduce the floor participation. Such joints interrupt the continuity of the pavement and generally involve considerable maintenance. Efforts should be made to reduce the number of such joints to a minimum. Participation from vertical loads may be eliminated by keeping the plane of the stringers at the neutral axis of the truss.

On the basis of the usual calculations, stresses in stiffening trusses are complete reversals. Under these conditions, W. M. Wilson, M. Am. Soc. C. E., has shown[22] that the usual alloy steels have strengths no greater than carbon steel; however, the loadings that produce these stresses are of rare occurrence. Silicon steel costs only slightly more than carbon steel, and for occasional over-stresses, should have an increased strength in the ratio of their yield points. It is believed, therefore, that silicon steel should be generally used for the chords of stiffening trusses.

The authors have furnished a method whereby comparative studies of any variable can be quickly made. It is better engineering to make these comparisons than to give any direct statement as to the economies of light-weight floors or other detail problems. As long as the designer considers the rigidity furnished in both vertical and horizontal planes by the dead load, the solution can be reached quickly.

The writers trust that this paper will become the basis for a specification for the design of stiffening trusses for vehicular suspension bridges.

HARDY CROSS,[23] M. AM. SOC. C. E. (by letter).—This paper is an important contribution both to the literature of suspension bridges and to the general theory of structural design. That it makes possible an immediate picture of the action of the truss and of the effect of variation of proportions of the structure is a rare virtue.

A case having important points of similarity to that discussed in the paper is presented by two parallel beams so connected that they deflect together. Assume that the dimensions of one of the beams (represented by the cable) is fixed and that its strength is of no further interest. Assume, also, that the second beam (stiffening truss) is added merely to stiffen the primary beam, whatever that may mean, and that structural failure of the secondary beam is to be feared only because it will then fail to stiffen properly. The shape of the deflection curve for a loaded beam and for a loaded cable are not alike; this does not destroy the usefulness of the comparison for present purposes.

---

[22] Rept. on Fatigue Tests of Riveted Joints, by Wilbur M. Wilson, presented at the meeting of the Structural Division, New York, N. Y., January 20, 1938. (Not published.)

[23] Prof., Civ. Eng., Yale Univ., New Haven, Conn.

The secondary beam may produce two effects: It may change the shape of the deflection curve; or, it may change the amount of the deflection. The authors present some evidence that the first effect is not important.

If the deflection of the primary beam is fixed, the angular distortions of the secondary beam are also fixed. Linear strains are then a function of depth and stresses are related to strains by the elastic modulus. Such a condition is represented in suspension bridges by cable stretch, expansion of cable, and movement of tower connections of cable due to the deformation of shore spans. These "deformation" stresses have no useful effect; they merely threaten the structural integrity of the secondary beam.

If the load on the combination is fixed, the presence of the secondary beam affects the moments on the primary beam and so affects the deflections. If the secondary beam is very flexible compared with the primary beam, this change in deflection is small, and the stresses vary as do the deformation stresses. Such a case is represented by such heavy bridges as the George Washington Bridge.

If the secondary beam is very stiff it will carry practically all the moment, and the deflection of the system under load will be primarily a function of the stiffness of the secondary beam. This is true of light suspension bridges; for these the elastic theory gives close approximations.

In most bridges the stress in the stiffening truss due to live load does not vary inversely as its strength. The truss is relatively inefficient as a stiffening member. The structure is "hybrid," acting partly as indicated by the elastic theory of suspension bridges where the moment to be resisted is fixed and partly as if its stresses due to load were of the nature of deformation stresses where the deflection produced is fixed.

One of the most important results of the paper may prove to be that more attention will be given to the question of the function of the stiffening truss. Stiffness may be discussed in terms of angular deformation, of deflection, of grade change. It may also be discussed in dynamic terms, and discussion of angular deformation, or of deflection, or of grade change, is not a completely adequate basis for estimating vibration characteristics. Probably stiffness needs discussion in all these terms. Engineers know that they want to stiffen the bridge, but they have not yet satisfactorily defined stiffness.

Valuable studies in the design of stiffening trusses, some of which are correlated to the thesis presented by the paper, have been made by Jacob Karol.[24]

A. A. EREMIN,[25] ASSOC. M. AM. SOC. C. E. (by letter).—In this paper the authors have developed a simple method of computing stresses in the preliminary design of suspension bridges. However, it has various limitations which should be considered by designers.

---

[24] "A Partial Influence Line Procedure for Suspension Bridge Analysis by the Deflection Theory," by Jacob Karol. Thesis submitted in partial fulfillment of the requirements for the degree of Doctor of Philosophy in Engineering in the Graduate School of the University of Illinois, 1938.

[25] Assoc. Bridge Engr., Bridge Dept., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

The error in computing stresses in stiffening trusses increases rapidly with a decrease in the span length of the bridge. From Table 1 it is evident that the error in computing the bending moment in the stiffening truss of the San Francisco-Oakland Bay Bridge by the preliminary method is about 1.77 per cent. The span length of the Bay Bridge is 2 294 ft. The error in computing the bending moment in the stiffening truss of the Maumee River Bridge, with its span length of 777.6 ft, is 7 per cent. The increased error in computing stresses in short-span suspension bridges is caused by the greater influence of approximate assumptions used in computing deformations of stiffening trusses in short-span bridges.

Equations (3) to (9), involving expressions for ordinates of suspension cables loaded with uniformly distributed dead and live loadings, were developed by the authors from equations in statics. Similar equations were developed in a slightly different manner in 1917.[26] It is to be regretted that, in computing the deformation of suspension cables, the authors considered only uniformly distributed loading. However, the maximum stresses in stiffening trusses of suspension bridges with moderate span length occur for a combined loading uniformly distributed, and concentrated forces at various points along the span length. Evidently, the computation of deflections and the deflection loops of suspension cables sustaining the combined loading is complicated and impracticable considering the simplicity of other available approximate methods of designing suspension bridges. The authors already have demonstrated the simplicity and other advantages of the design methods based on trigonometric functions. Approximate analyses of stresses in suspension bridges with moderate span lengths may also easily be made with model test, as shown by Mr. E. Rothenberg.[27] Likewise, an interesting preliminary study of the Bay Bridge was performed by the use of a model.[28] In the model tests various combinations of uniformly distributed and concentrated loading may be considered. Furthermore, the stiffening truss may be considered either with uniform or variable moment of inertia along the span length.

A. Fraser Rose,[29] M. Am. Soc. C. E., and William A. Rose,[30] Assoc. M. Am. Soc. C. E. (by letter).—This timely paper is quite in line with the modern trend in structural analysis and design—simplification through successive approximations—and is a worthy addition in this field to the method of moment distribution.[31] The proposed method is developed in such a manner that it possesses the added advantage of affording the designer a clear mental picture of the contributions to the final results made by the various factors.

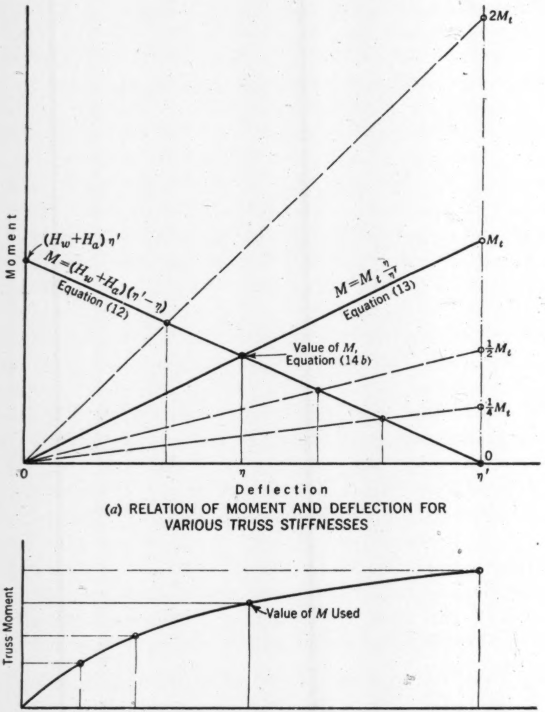
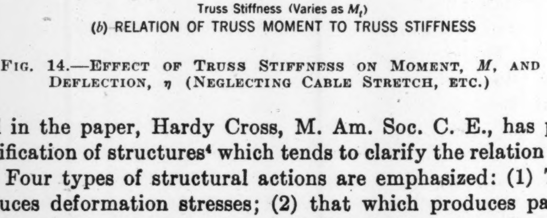
[31] "Analysis of Continuous Frames by Distributing Fixed-End Moments," by Hardy Cross, M. Am. Soc. C. E., *Transactions,* Am. Soc. C. E., Vol. 96 (1932), p. 1.

The great difficulty in analyzing a structure of the nature of the stiffened suspension bridge is that superposition of results is not permissible, inasmuch as they are inter-related. The authors have overcome this obstacle by the clever device of considering the contributing factors in their relative order of importance, and subsequently correcting for the errors introduced by trial superpositions.



(*a*) RELATION OF MOMENT AND DEFLECTION FOR VARIOUS TRUSS STIFFNESSES



(*b*) RELATION OF TRUSS MOMENT TO TRUSS STIFFNESS

FIG. 14.—EFFECT OF TRUSS STIFFNESS ON MOMENT, M, AND DEFLECTION, η (NEGLECTING CABLE STRETCH, ETC.)

As cited in the paper, Hardy Cross, M. Am. Soc. C. E., has proposed a logical classification of structures[4] which tends to clarify the relation of analysis to design. Four types of structural actions are emphasized: (1) The action which produces deformation stresses; (2) that which produces participation stresses; (3) normal structural action; and (4) hybrid structural action. The proposed method clearly indicates that the stiffened suspension bridge exhibits characteristics of all four of these types of action, but that it is primarily a hybrid structure. As the authors point out, there are any number of possible designs for the stiffening truss in a given instance. Any change in truss stiffness is reflected in a change in the moment resisted by the truss, a typical hybrid action. Where hybrid action exists, preliminary designs for comparative study are profitable and enlightening.

The use of exact, or relatively exact, methods of analysis for preliminary studies is not justified. The small added degree of accuracy attained consumes an unwarranted length of time and serves no useful purpose. The importance of developing, on rational bases, approximate methods for rapid analysis in such cases cannot be over-estimated. Their availability is conducive to a proper study of the effects on the analysis of the variation of the several factors which enter into the design. In this way, the engineer is enabled to secure the maximum economy consistent with stability.

The writers agree with the obvious conclusion of the authors that the determination of the maximum shears is not essential for preliminary design purposes. One finds in designing the web members of the stiffening trusses that minimum section rather than stress governs the areas in many cases. Even in the final design, maximum shears are needed at only a few points; for the preliminary work, sufficient information may be obtained from the maximum moments at critical sections.

A number of interesting conclusions may be reached after careful inspection of the equations that enter into the calculation of the moments at a critical section. For example, consider Equations (14*b*), (24*a*), (37*a*), (40*b*), and (42) in their relation to the determination of maximum moments at the quarter-point of the main span.

The final total moment at the quarter-point is the sum of the values obtained from Equations (14*b*) and (37*a*). In the first of these values, it is evident that an increase in M_t, which from Equation (24*a*) is proportional to I, results in a less than proportional increase in M, due to the fact that M_t appears in the denominator as well as in the numerator of the expression on the right-hand side. This is clearly shown in Fig. 14, in which the final moment is the ordinate of the point of intersection of the lines, $M = (H_w + H_a)(n' - n)$, and $M = M_t \frac{n}{n'}$ (Equations (12) and (13)).

Fig. 14 and Equation (14*b*) emphasize the existence of hybrid action. Hybrid action is further shown by inspection of the factors that contribute to the change in sag, df. From Equation (37*a*), it might hastily be concluded that df should vary inversely with I. This conclusion tacitly assumes that M would remain fairly constant. Careful study reveals that M, due to this cause, increases almost as rapidly as I, so that the decrease in df is considerably less than proportional.

Three factors contribute to df. Temperature change contributes a constant deformation in the cable and a constant change, df, in sag, regardless of truss stiffness, except for a small correction due to the additional stress in the cable caused by the temperature change. This action by itself then comes under the first of Professor Cross' classification—action which produces deformation stresses.

The second factor is the change in cable stress from that under dead load at mean temperature, caused by the addition of live load; this contributes almost a constant amount to *df* except for small changes due to its own action.

The third factor is the element termed side-span interaction. The contribution to *df* from this cause is by no means constant, but is affected by any change in side-span stiffness. This is brought out in Equations (40*b*) and (42), and in Table 2. Side-span interaction comes under the second of Professor Cross' classifications—action which produces participation stresses. It should be noted that maximum negative moment in the side span itself is primarily participation moment.

The preceding discussion on the change in sag is necessarily somewhat general because the three factors really merge into one another in a simultaneous action. Nevertheless, the proposed preliminary design method does give an idea of the related action of the various factors, a picture which is lost in mathematical formulas in the more exact methods.

The authors are to be congratulated upon their choice of subject and their manner of presentation. Considerable effort has apparently been made to keep the percentage error in the various approximations consistent, so that needless computation is avoided. The illustrative material has been carefully chosen to cover a wide range of cases. Obviously, the method may be extended for the computation of maximum moments at sections other than those given, should such extension be necessary or desirable in a given case.

LEON S. MOISSEIFF,[32] M. AM. SOC. C. E. (by letter).—The literature on suspension bridges has received an interesting contribution in this paper. A clear understanding of the distortional behavior of suspension bridges, and of the functioning of stiffening trusses, is not as common among engineers as it is generally assumed to be. The facts that, with the exception of suspension bridges, all other bridges may be treated as rigid structures and that suspension bridges are relatively small in number, rightly lead to directing the attention of engineering students to rigid bridges. The distortions of rigid bridges under live load, wind, and temperature are small enough not to affect the primary stresses of their frames. This does not hold true for suspension bridges. In these bridges the distortion of the structure under live load and other outside causes exerts a marked and determining effect on the stresses in the various members of the combined structure. Suspension bridges, therefore, require a different analytical approach than rigid bridges and, as a consequence, the considerations covering their design are also different.

The authors' approach to the problem, through a study of the behavior of an unstiffened cable, is efficient for the purpose of a qualitative appreciation of the functioning of suspension bridges. Such studies were made a century ago by Navier, Rebhan, and others. That these studies dealt with the unstiffened cable was an outcome of the fact that, in those days, suspension bridges were not stiffened systematically. For the light wagon loads of those times a braced railing was considered sufficient. These studies contained much informative material, and offered a good insight into the general behavior of suspension bridges.

---

[32] Cons. Engr., New York, N. Y.

After experience had shown that light, unstiffened suspension bridges were neither comfortable for travel nor safe against wind, engineers began to stiffen them. For the short-span bridges built in the early times the attachment of any sizable stiffening girder supplied more than sufficient stiffness. In fact, the girders were so stiff that it appeared to be logical to assume the beam as perfectly rigid. A simple static solution then became possible and was readily established. It formed the basis of the well-known Rankine-Ritter theory. This was the suspension bridge theory taught in engineering schools fifty years ago, which assumed a rigid truss suspended from the cables. The assumption of absolute rigidity of the stiffening truss tacitly involved the unchanged form of the original curve of the cable, and precluded the recognition of the deformations of the structure. The effect of the "dead," or original, load on a suspension bridge could not be considered. The Rankine-Ritter theory ignores it. To this statement should be added that at that period of engineering the elastic behavior of bridges had not as yet come into practical application. In general, bridges were small, relatively stiff, and the elasticity of the members could equally be ignored.

With the greater use of metallic bridges the effect of temperature variation was recognized in the course of time, and a correction was introduced in the stiffening-truss formulas to allow for the change in length of cable due to change in temperature. Soon, thereafter, the elongation of the cables due to change of load also received recognition, and the correction was extended to provide for it.

By that time the study of the elastic behavior of metallic structures had attained a high development and was extended to suspension bridges. The elastic theory, which was then developed, took account of the elasticity of the various parts forming a suspension bridge and forgot the effect of the dead or original load of the bridge. The deflection theory takes this effect into consideration as its basic idea. It has proved that the effect of the dead load or, more precisely, the pull in the cable due to it, is of serious importance and sometimes completely controls the design and behavior of the bridge. The elastic theory has outlived its usefulness as a tool for designing suspension bridges.

The authors are aware of these developments, and they approach the problem with an educated understanding. Step by step, consistently adhering to the function of the stiffening truss and its conditioned behavior in the bridge, the authors approach an intelligent approximation of the more accurate solution. Taking into account the results of the computations of some modern suspension bridges, they make empirical approximations adjusted to these results and arrive at a procedure for a preliminary design.

The comparisons, given in Table 1, of the results obtained by the preliminary method as against those obtained by the deflection theory, are close and satisfactory for the purpose. The range of the data, however, has too narrow a compass.

In the Golden Gate Bridge, in San Francisco, Calif., with a main span of 4 200 ft, dead load of 21 000 lb per lin ft, and live load of 4 000 lb, the greatest positive moment is found at 0.126 of the span length from the tower, and it is 10% greater than at the quarter-point. Attention is also called to the fact that the stress due to live load in the Golden Gate Bridge is only 30% of the total stress and that the remaining 70% is due to the transverse wind.

In the Whitestone Bridge, in New York, N. Y., with a span of 2 300 ft, dead load of 11 000 lb per lin ft, and live load of 3 000 lb, the moment at the quarter-point, by the authors' approximate method, is 5 172 kip-ft, and by the deflection theory, it is 5 000 kip-ft, which is very close; but, again, this moment is not the maximum moment. The maximum moment occurs at one-tenth the span length from the tower, and amounts to 6 360 kip-ft. This is 23% greater than at the quarter-point. Evidently, the assumption that the maximum moment is at the quarter-point in all bridges is incorrect, and the method proposed should be handled with care.

The writer disagrees with the authors that the steps involved at arriving at results by the approximate method will take less time than by using the deflection theory procedure directly. After all, it depends entirely on one's familiarity with this procedure. That a computation machine should be used for rapid and accurate results is true; but an engineering office engaged in designing suspension bridges is supposed to be so equipped.

O. H. Ammann,[33] M. Am. Soc. C. E. (by letter).—The authors have made a useful contribution to the design of stiffened suspension bridges. The principal merit of their method of analysis lies in the fact that it aids the student more clearly to visualize the behavior of the unstiffened cables and the effect thereon of the stiffening trusses and other factors, and to evaluate the economic value of stiffening trusses of various degrees of rigidity.

The paper does not attempt to go beyond the mathematical analysis as an aid to preliminary design studies; but in their conclusions the authors indicate that there are a number of problems in the design of stiffening trusses which require clarification. They may be summarized in the two important questions: What is the appropriate degree of rigidity? and how is it to be obtained structurally?

Judging from the widely varying degrees of rigidity of stiffening trusses, even in recently built suspension bridges, it would seem, indeed, that these questions offer a fruitful field for further study with a view to establishing a more uniform, and possibly improved, practice. However, a comprehensive study of the problem leads to the conclusion that both the criteria for rigidity and the factors involved in the design of an adequate and economical stiffening system are so complex, and to some extent necessarily matters of individual judgment, that an attempt to devise formulas or rules of design on a theoretical basis appears fruitless.

The problem is peculiar to suspension bridges because, contrary to its effect in truss types, rigidity is secured by increased expense and must be kept to a minimum. This, in fact, becomes one of the major economic factors in suspension bridges of long span.

---

[33] Director of Eng., The Port of New York Authority, and Chf. Engr., Triborough Bridge Authority, New York, N. Y.

The very object of rigidity in a bridge is complex. In smaller and lighter structures the principal object is rigidity against vibrations or oscillations which may be detrimental to the structure as well as objectionable to traffic. No valid formula has ever been devised on theoretical grounds as a measure for the required degree of rigidity in this respect. Experience has set up very crude and purely empirical criteria in the form of limiting deflections.

As the bridge increases in span and weight this object becomes less and less important, except in the design of the floor system. In fact, flexibility of the structure as a whole becomes advantageous, because it tends to reduce local impact effects and vibrations. The principal purpose of limiting deflections and other deformations of the main carrying system in long spans is to avoid excessive gradients, and to prevent deformations that may result in excessive local bending, distortions, or transverse tilting of the floor structure.

Limiting grades may be important in bridges carrying rail traffic, but for modern highway traffic even that object loses significance, because the grade changes that may be actually produced in a well designed structure are not sufficient to form a serious impediment to traffic.

The effect of the deflections upon the floor depends so much upon the width, depth, and general arrangement of the floor structure as to require careful study in each individual case.

The authors state that present tendencies are to make stiffening trusses more flexible. This is undoubtedly due to the recognition of the fact that with increasing magnitude of bridges, and particularly those serving modern highway traffic, rigidity, as measured by deflections of the structure as a whole, ceases to be a virtue, and that flexibility offers material economic advantages, besides aiding the designer to produce more graceful structures.

This recognition is due partly to the abandonment of the so-called elastic theory which ignored the influence of the dead weight of the structure upon the proportioning of the stiffening system and thus, with increasing magnitude of span, led to more erroneous and wasteful design. The general rule, found in many former treatises and textbooks on suspension bridges—that the most appropriate depth of stiffening trusses, irrespective of span length, character of moving load, or dead weight of suspended structure, was between $\frac{1}{40}$ and $\frac{1}{60}$ of the span—was based upon that erroneous theory.

The writer became aware of the economic significance of flexible trusses in his preliminary studies for the George Washington Bridge. In the attempt to determine the proper proportions of the stiffening trusses for a span of such unprecedented length, he resorted to a careful study by analysis, as well as by model, of the behavior of the unstiffened cables, in respect to deflections, grade changes, and angular distortions under various load conditions.

These studies convinced him that this bridge, which was to be designed principally for highway traffic with the possibility of later addition of suburban transit trains, would have ample rigidity to accommodate highway traffic without any stiffening system whatsoever—that is, without any restraint upon grade changes and deflections of the unstiffened cables—but that, even for rapid transit trains, although the unstiffened system as a whole would be amply rigid in so far as deflections and grade changes are concerned, comparatively flexible trusses between the two decks, with a depth ratio of only $\frac{1}{120}$, were advisable to secure local rigidity and avoid excessive local distortions of the floor.

The bridge was actually designed in accordance with these conclusions, and to date (1938) it has only a single completely unstiffened deck. This was a radical departure from conventional practice,[34] but experience has corroborated the validity of the conclusions.

The Golden Gate Bridge, at San Francisco, Calif., which has since been completed with a span of 4 200 ft and carries only highway traffic on a single deck, was designed with trusses 25 ft deep, which is only $\frac{1}{168}$ of the center span. Thus far, it also has proved amply rigid. It is the writer's present opinion that even shallower trusses or solid plate girders would be just as adequate for this great span.

A further radical step in the direction of greater flexibility of stiffening trusses was taken in the design of the Bronx-Whitestone Bridge across the East River in New York, N. Y. It has a center span of 2 300 ft, side spans of 735 ft, and is designed to carry only highway traffic on a single deck 75 ft wide. It is stiffened by plate girders of a depth of 11 ft, which is only $\frac{1}{210}$ of the span length. The moment of inertia of the girders is only 2 600 in.^{2}–ft^2 in the center span, and 2 140 in the side spans. These values are practically the same as the corresponding ones of the stiffening girders (10 ft deep) used in the Maumee River Bridge in Toledo, Ohio, which has a center span of only 778 ft, and side spans of 230 ft.

The Bronx-Whitestone Bridge still requires the test of actual operation. If it proves to be amply rigid, as the writer does not doubt, it should set a precedent for spans of that magnitude and similar proportions. It should also indicate that some of the bridges of shorter span might well have been designed with shallower, more economical, stiffening trusses or girders, particularly such structures in which the deflections of the unstiffened cables are reasonably restrained by the compound effect of other influencing factors, such as relatively wide and heavy floor structure, shallow cable sag, and short side spans.

Suspension bridges for heavy modern highway traffic are a comparatively recent development. They will never be common structures and each case will call for and merit most careful study. In view of the complexity of the factors which influence the design of the stiffening system, the trial method of approaching a final design, together with judgment based upon experience, will be found as serviceable as and less likely to lead to erroneous practice than "cut and dried" formulas or rules of design.

LEON BLOG,[35] ASSOC. M. AM. SOC. C. E. (by letter).—A method for the preliminary design of two-hinged stiffening trusses of cable suspension bridges is presented in this paper. The object of developing a preliminary method for proportioning any structure is the rapid consummation of the final design. The use of the method must assure the designer that the proportions selected for the application of the preliminary method will result in the ideal design when used in a more accurate method. The preliminary method presented by the authors enables the designer to arrive, rapidly and understandingly, at deflections and moments, thereby yielding an idea as to the combined stiffness of the cable and stiffening truss, the effect of the live load on the total cable tension, and the unit stresses in the truss selected.

[34] *Transactions*, Am. Soc. C. E., Vol. 97 (1933), p. 43.

[35] Asst. Chf. Structural Engr., Div. of Bridges and Structures, City of Los Angeles, Los Angeles, Calif.

The writer has investigated the possibility of further reducing the total time for the preliminary design required by ignoring the width of the top of the tower. This tower width is a factor in the authors' method and, of necessity, considerable time must be spent in investigating for a rational width of tower top in order to arrive at L', the short cable section over the saddle. The horizontal component of the live load tension as well as that of temperature is a function of $I \div I_1$. The horizontal components are first converted into tensions along the cable and these tensions, in turn, into vertical components acting on the tower. The tower can then be designed. Thus, the final tower design cannot proceed without satisfactory stiffening trusses. If a suitable method of determining such trusses can be developed independently of a predetermined tower-top width, considerable time will be saved.

Accordingly, the writer has explored the degree of accuracy to be obtained by using the authors' method with all steps involving L' deleted from their solutions. To do this, the cable curves were produced backward to the center lines of the towers, new sags, cable lengths, and horizontal spans were computed and then used in the authors' solutions with Operations 6(*c*), 7(*c*), and 8(*c*), in Table 2(*a*), eliminated.

Design constants in Table 1(*a*) are compared with the results of the writer's simplification in Table 4.

TABLE 4.—COMPARISON OF DESIGN CONSTANTS

Method	LENGTH OF SPAN, IN FEET		LENGTH OF CABLE, IN FEET		SAG AT CENTER OF SPAN, IN FEET	
	Main span, l	Side span, l_1	Main span, L	Side span, L_1	Main span, f	Side span, f_1
Table 1(*a*), Column (2).......	1 358	660.7	1 394.00	685	133.70	31.600
Writer's simplification........	1 380	671.7	1 416.82	696	138.07	32.337

The authors have observed that the horizontal projection of L' practically equals the true value of L' which is supported by noting that $L = 1\,416.82$ ft $= 1\,394 + 22.82$ ft, the additional 0.82 ft arising from the fact that the main and side-span cables intersect at the center line of the tower in a cusp, the sum of whose sides is greater than $L' = 22$ ft. Note that the side-span cable has been increased 11 ft to 696 ft, from 685 ft. In short, the total length of the bridge cable is practically unchanged. Dropping the 0.82 ft and using

1 416.00 ft did not affect the writer's solutions. The writer's values in Table 4 were used in solving Tables 2(*a*), 2(*b*), 2(*c*), and 2(*e*). The answers obtained by the authors and by the writer's simplification of their method are compared in Table 5.

The writer did not solve the cases of Tables 2(*d*) and 2(*f*) because no step-by-step check was available. However, the nature of the computations in the authors' method indicates that results close to those of the authors for these unsolved cases would result by using the writer's simplification.

Table 5 shows that the maximum deviation for moment for any case studied was about 2% less than the authors' result and occurs in Table 2(*b*). Assuming that the stiffening trusses being investigated are actually working up to a maximum allowable fiber stress of 18 000 lb per sq in., the writer's result yields 0.02 × 18 000 = 360 lb per sq in. less, or the stress in the chords would be 17 640 lb per sq in. Inspection of Table 5 shows that the variations for other cases in Table 2 are not large. Since the essence of the simplification being demonstrated is the use of longer stiffening trusses than those proposed, with the incidental greater loads, there is never any danger of adopting trusses that will be too weak.

TABLE 5.—COMPARISON OF MAXIMUM MOMENTS AND CORRESPONDING DEFLECTIONS

Item No.	Method	QUARTER-POINT, MAIN SPAN* (TABLE 2(*a*))		CENTER, MAIN SPAN* (TABLE 2(*b*))		QUARTER-POINT, MAIN SPAN† (TABLE 2(*c*))		CENTER, SIDE SPAN* (TABLE 2(*e*))

* Maximum positive moments; deflection is down. † Maximum negative moment; deflection is up.

‡ $\frac{\text{Item No. 2}}{\text{Item No. 1}}$.

Table 5, Column (9), further shows that the maximum deviation between the two methods for any downward deflection is plus 4% and equals about 2 in.; and, Table 5, Column (7), shows the deviation for the upward deflection to be 5% and also equals about 2 in. Even for so stiff a structure as the modern Triborough Bridge (New York City), a 2-in. variation in accuracy between two preliminary methods is not serious.

The results obtained by the writer's simplification are evidently similar to those of the authors. No preliminary tower design is required. Time is saved. One more trenchant tool has been added to the engineer's kit by the authors. Once the underlying formulas are understood and accepted, only the simplest mathematics is required. Visualization of the otherwise intricate interaction of all parts of the hybrid assembly has been made easy.

"Preliminary Design of Suspension Bridges" will take its place beside "Analysis of Continuous Frames by Distributing Fixed-End Moments"[36] as a drudgery reducer in structural analysis.

SHORTRIDGE HARDESTY,[37] AND HAROLD E. WESSMAN,[38] MEMBERS, AM. SOC. C. E. (by letter).—The writers greatly appreciate the comments made by those who have discussed this paper. Mr. Ammann emphasizes the major significance of the method when he notes, first, its value as an aid in visualizing the behavior of the unstiffened cables and the effect thereon of the stiffening trusses and other factors; and, secondly, its merit in appraising the economic value of stiffening trusses of various degrees of rigidity. In fact, its value in a variety of economic studies is demonstrated clearly by Messrs. Woodruff and Raab in their interesting discussion.

In the preliminary studies which are necessary for any suspension bridge, it is not only important to have a method which will give approximate maximum moments and deflections quickly at one or two points, so that trusses of different rigidity may be compared, or that other variables may be investigated; but it is even more important that the method permit and facilitate an understanding of the action of all parts of the structure. Here is where the deflection theory, championed by Mr. Moisseiff, displays its shortcomings, for the very nature of the exponential formulas, as is evidenced by even a casual inspection, is such that the related functioning of truss and cable, side span and main span, is completely disguised. In the application of these formulas to the determination of stiffening truss moments, no scale is obtained regarding the relative contributions of each factor to the total moment. In preliminary studies, at least, it is important to know how variations in one factor or another will affect final results, in order to obtain an economical design. In commenting about the preliminary design method, Mr. Blog states: "Visualization of the otherwise intricate interaction of all parts of the hybrid assembly has been made easy."

The important studies made by Mr. Karol again emphasize this. Figs. 8, 9, and 10 give an excellent break-down of the contributions of various factors to the moment and deflection at the quarter-point of the main span of the Triborough Bridge.

It is important to note that the writers emphasize the method in its relation to preliminary design studies. It is the preliminary study of any project which calls for the highest degree of engineering judgment, talent, and experience. The final design and its analysis are usually of a routine nature. They demand technical skill, it is true, for their consummation, but they rarely result in major changes in conclusions already reached as a result of thorough preliminary studies. Mr. Fischer, apparently, does not recognize a distinction between, nor the relative importance of, preliminary and final design. Which is more important—making the decision that the stiffening truss of the Bronx-Whitestone Bridge shall be an unprecedented shallow plate girder only 11 ft deep $\left(\frac{1}{210}\text{th of the span length}\right)$—or computing the final curve of maximum moments for the girder as selected?

---

[36] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1.

[37] Cons. Engr. (Waddell & Hardesty), New York, N. Y.

[38] Prof., Structural Eng., Coll. of Eng., New York Univ., New York, N. Y.

In making the analysis of the final design, the deflection theory in one form or another should be used. Mr. Moisseiff prefers the deflection theory expressed in exponential formulas, which require a computing machine for accurate results. The writers prefer the deflection theory expressed in terms of a trigonometric series, which gives just as accurate results with an ordinary slide-rule. That is a matter of personal preference.

Mr. Fischer believes that the elastic theory can be used for spans less than 750 ft long. The writers see no merit in using a theory of analysis which is definitely erroneous. They heartily agree with Mr. Moisseiff when he states, "The elastic theory has outlived its usefulness as a tool for designing suspension bridges." Moreover, any preliminary design method based on the elastic theory may lead to distinctly erroneous conclusions, when one realizes that there are a thousand possible stiffening trusses of various rigidities for any suspension bridge. The elastic theory, which ignores cable deflections and dead-load effects, if applied to the Bronx-Whitestone stiffening girders as designed, is 1 300% in error. Other stiffening girders or trusses might have been used in which the error, by using the elastic theory, would be less; but they would be stiffer—and more expensive. A preliminary design method that does not disclose the true structural action is of little value to the engineer who must make his choice primarily in terms of rigidity and economy.

In making economic studies, diagrams, such as Figs. 11 and 12 plotted by Mr. Karol in applying the writers' method, are a distinct help in getting the answer to the following question raised in the paper:

"Is it more economical to obtain stiffness by increasing the chord section or by increasing the depth of the truss?"

In a simple truss, increasing the chord area lowers unit stress. Increasing the depth of truss also lowers stress. On the other hand, if the depth of a stiffening truss is increased, the unit stress is actually increased. If unit stresses are too high, decreasing the depth and increasing the chord area will bring them down; but, at the same time, the effect upon rigidity must be kept in mind.

Messrs. Woodruff and Raab have presented an interesting summary in Table 3 showing the effect of moment of inertia on rigidity, associated with changes in dead load of floor slab and dead load of trusses and cable. It is desirable to keep dead load down in order to save on cable and tower steel. Using a light-weight deck will help to do this, but the light-weight deck and the supporting floor steel may cost more than a standard concrete slab and its framing. Will the saving in one item offset the increase in another item?

Moreover, if a definite rigidity (whatever that may mean) is to be attained, higher dead load is of help in reducing deflections, but it may be cheaper to use a stiffer and more costly stiffening truss to get the same result, in order to save on cables and towers.

Mr. Eremin states that there are various limitations to the writers' method which should be considered by designers, but he fails to point out any limitations of significance.

The writers are indebted to Mr. Moisseiff for calling their attention to the fact that the point of maximum positive moment in the Bronx-Whitestone Bridge is at a point one-tenth of the span length from the tower. The moment at that point (6 360 ft-kips) has been verified by the writers, using the trigonometric series method. On the Golden Gate Bridge, the point of maximum moment is near the eighth-point. It is an interesting fact that, on these two large spans with unusually flexible stiffening units, the point of maximum moment does not occur at or near the quarter-point. That does not nullify the value of the writers' method as an aid in preliminary design studies. As stated by Messrs. Rose and Rose, the method may be extended for the computation of maximum moment at sections other than those given. It is questionable, however, whether this is worth doing for preliminary studies, although the point is one that warrants additional investigation. In making initial designs, it is advisable to correlate stiffening truss moment at some section with deflections at the same section, in order to get a scale on rigidity, as indicated by Fig. 7.

Fig. 15 has been plotted to show how the unstiffened cable deflects under an advancing uniform live load with the cable length kept constant. Note that the maximum deflection occurs almost at the quarter-point with live load extending over a distance of $0.4\,l$ into the main span. A load extending about $0.2\,l$ into the main span causes a loop with maximum deflection near the eighth-point, but the deflection is considerably less than the maximum at the quarter-point. When cable-stretch effects are included, the difference between the two becomes even greater. It was because of this, and also because maximum positive moments on a large number of spans already designed occurred at or near the quarter-point, that the writers developed the preliminary design method primarily in terms of quarter-point effects.

Fig. 15 indicates the possibility of further interesting studies on suspension bridges. It is not the deflection, but the curvature of the curve of deflection of the cable which is important in evaluating stiffening truss moments. The stiffening truss must have the same curvature as the curve of deflection of the cable, neglecting suspender deformations.

The differential equation of curvature for the cable given in Equation (21c) may be restated, as follows:

$$\frac{d^2\eta}{dx^2} = -\frac{w_s - \beta\,w}{H_a + H_w} \qquad \text{(50)}$$

The differential equation of curvature for the stiffening truss is:

$$\frac{d^2\eta}{dx^2} = -\frac{M}{E\,I} \qquad \text{(22)}$$

In the unstiffened cable, an inspection of Equation (50) indicates that the curvature of the curve of deflection of the cable, with cable-stretch effects omitted, may be slightly greater at the eighth-point than at the quarter-point. It is dependent somewhat on the ratio of live to dead load. The denominator decreases if H_a (live load horizontal component of cable stress) becomes less. The numerator will increase, because $\beta\,w$ decreases.

When a flexible stiffening truss, such as that of the Bronx-Whitestone Bridge, is added to the cable, the stiffening effect is somewhat localized in nature. The moment corresponding to Step I of the preliminary design method is then greater at the eighth-point than at the quarter-point. The quantity $w_s - \beta w$ (which is the suspender pull minus a fractional part of dead load) is directly related to the moment, as evidenced by Equations (50) and (22). A study of Fig. 6 clarifies this relationship.

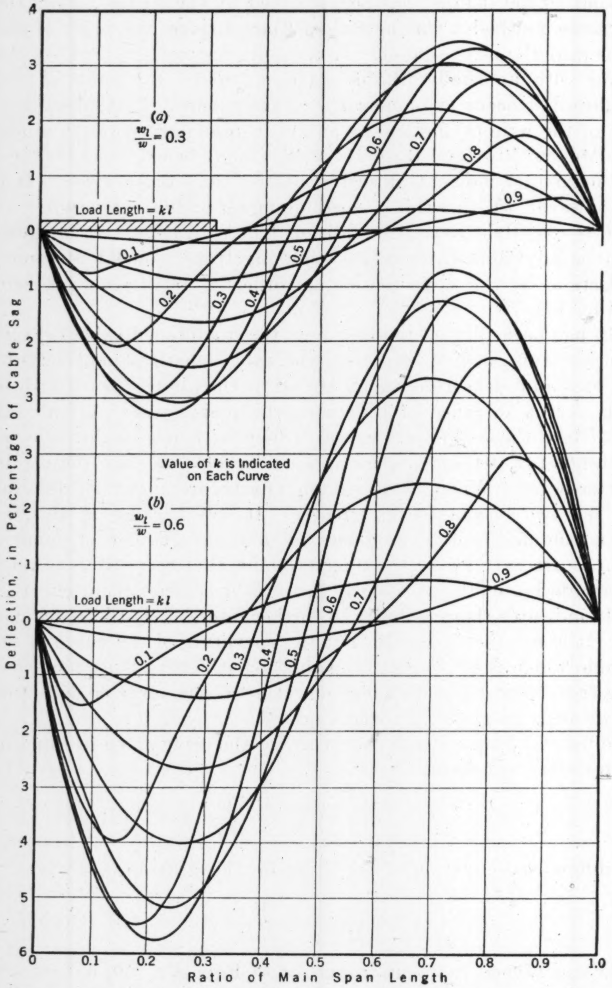

FIG. 15.—DEFLECTIONS OF UNSTIFFENED CABLE DUE TO PARTIAL LIVE LOAD OF VARYING LENGTH EXTENDING FROM LEFT END OF MAIN SPAN. DEAD LOAD OVER ENTIRE SPAN

The moment from Step II, however, involving cable-stretch effects, is definitely greater at the quarter-point than at the eighth-point. As noted under the heading, "Effect of Cable Stretch, Temperature Change, and Side-Span Interaction: Effect of a Change in Sag Upon the Main-Span Stiffening Truss," the moment diagram is elliptic in shape rather than parabolic, with the maximum moment at the center of the span. As flexibility increases, however, the moment due to Step II becomes a smaller part of the total, as shown in Fig. 9. Consequently, even if the moment from Step II is greater at the quarter-point than at the eighth-point, the difference is not as great as the difference in Step I where the effect at the eighth-point predominates. Hence, the point of absolute maximum positive moment may have a considerable range depending upon the "stiffness" of the stiffening truss. A detailed study of characteristics of maximum moment curves would be of some value, in view of the tendency toward more flexible stiffening units. It is quite possible that the maximum moments in some cases may be almost constant over that part of the span, say between the tenth- and the fifth-point. This is an added argument supporting the tendency to use virtually the same section throughout for the stiffening girder or truss, a practice which, of course, appeals to the fabricator.

Mr. Moisseiff undoubtedly recognizes that, as one gets closer to the tower, the effect of suspender elongation, and the effect due to the location of the end pin of the stiffening girder not being in the same vertical line as the end of the cable above, upset considerably the moments and shears derived by the usual deflection theory formulas.

Messrs. Rose and Rose have submitted a valuable discussion, linking the suspension bridge to the classification of structures proposed by Professor Cross,[39] a classification which is of tremendous importance to the profession. When its significance becomes more widely recognized, practicing engineers will design structures even more intelligently than they do now; teachers of indeterminate structures will be more careful in relating procedures of analysis to design.

The writers are also indebted to Messrs. Rose and Rose for calling attention to the relatively unimportant part played by shears in preliminary design studies. Incidentally, Mr. Karol notes that he has extended the method to account for maximum shears. It is important to note again that maximum end shear cannot be determined accurately by any theory that ignores the location of the end pins of stiffening trusses relative to cable.

Mr. Blog submits a simplification of the method which is quite acceptable. It will undoubtedly save time to eliminate the small elements of length denoted by L', and to work with all initial dimensions referred to the center line of the tower. Table 5 indicates that the results obtained by this simplification are accurate enough for preliminary studies.

Professor Cross draws upon the structural action of the flitched beam in clarifying the picture of the interaction of cable and stiffening truss. It is also important to keep Fig. 6 in mind in picturing the load distribution between the two elements. He also expresses the hope that more attention will be given to the function of the stiffening truss, with a view to defining stiffness adequately. There is undoubtedly a definite need for further research in this field, a need that challenges the resourceful investigator. The problem is not a simple one.

[39] "The Relation of Analysis to Structural Design," by Hardy Cross, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1363.

This is further emphasized by Mr. Ammann in his enlightening discussion concerning rigidity and recent trends toward more flexible trusses. The writers are indebted to him for noting that the factors which influence the design of the stiffening system are so complex that the trial method of approaching a final design, combined with judgment based upon experience, is less likely to lead to erroneous practice than "cut and dried" formulas or rules of design.

ADVANTAGES OF ORDERLY PLANNING

BY FREDERIC H. FAY,[1] M. AM. SOC. C. E.

SYNOPSIS

Attention has been focused upon public works as a possible stabilizing factor on employment, by the vast sums spent by the Federal Government in this field in the past few years for unemployment relief. The paper presents facts as to the construction industry as a whole, its relation to national income, and the share of public works in the industry, for the years 1925 to 1935, inclusive, the period for which detailed statistics were available. For public works themselves, analysis is made of expenditures in this period by the Federal Government, by the States, and by local governmental units.

During the depression expenditures in the construction industry as a whole (which in the pre-depression period accounted for one-sixth of the national income) dropped far more rapidly than the national income, primarily because of the great slump in private construction. Public works declined considerably after 1930, notwithstanding the greatly increased expenditures of the Federal Government, since the excess of Federal expenditures was nullified and much more than offset by the sharp drop in expenditures by counties and municipalities. Contrary to the general impression that the past few years has been a period of substantially increased activity in public works, the facts are that the country's public works program was a full year behind schedule by the end of 1935.

The theory of a controlled public works policy, by which construction will be retarded to some extent in prosperous times and expanded to relieve unemployment in periods of depression, is noted. This principle has not yet been given a fair trial since what has been done thus far has been done under pressure of an emergency and without the benefit of advance planning. The recent depression has taught its lessons, however, which may serve to guide future policy. Some of these lessons are stated. The importance of advance planning of public works and long-term budgeting, whether or not a policy of controlled public works as a stabilizing factor is to be attempted, is reviewed. Suggestions are offered whereby orderly advance planning may be made effective, thereby promoting efficiency in administration and economy in government.

INTRODUCTION

The efforts of the Federal Government during the past five years or more to stimulate public works as a means of relieving unemployment and lessening the severity of the depression throughout the United States, has forcibly impressed upon engineers engaged in carrying out this program, and to some slight extent has awakened the public to, the need of orderly advance planning of public works. Although long advocated by a few economists, engineers, planners, and others of vision, it is only during the recent depression that an attempt has been made in this country on a large scale to stimulate business and alleviate unemployment by accelerating and expanding public works construction.

---

[1] Cons. Engr. (Fay, Spofford & Thorndike), Boston, Mass.

Although it has been measurably successful, this attempt has failed to produce the full degree of stimulation anticipated. However, the experience of the five years (1932 to 1937) affords no adequate criteria for passing judgment on the merits and defects of the principle of planned flexibility in public works, for the reason that (with certain exceptions as regards Federal programs) the element of advance planning has been absent. In State, county, and municipal public works particularly, which constitute by far the greater part of the public works field, carefully prepared plans were almost non-existent. Instead, in a desperate effort to meet an unexpected emergency, project after project was authorized and constructed by means of hastily conceived, unstudied plans which all too often had to be improvised almost over night. The many obstacles in the way of initiating public works at short notice in the absence of carefully prepared plans presented almost insuperable difficulties.

On the engineering side, this lack of thorough preliminary investigation and planning has frequently resulted in uneconomical expenditure through modifications of plans necessary to meet unforeseen conditions arising during construction, the resulting extra cost of which might have been avoided had it been possible to exercise careful engineering foresight based on adequate data as to physical conditions to be met. On the economic side (and this often was of even greater importance) insistence on immediate action left no time for deliberate investigation of the economic worth of many projects undertaken, nor a wise selection between projects according to their comparative merits and need.

The orderly planning of public works in advance of public requirements, both as to their engineering and their economic aspects, is at all times a sound governmental policy. This is so fundamental as to require no argument. That such sensible foresight has not been exercised in greater degree in the past is due largely to lack of understanding by the public generally as to the nature and importance of planning. On the physical side there is little comprehension by the public of the time, effort, and money necessarily required for securing adequate knowledge of site conditions and for the preparation of designs which shall meet conditions in a proper and economical manner. Such engineering investigation, instead of being needless expense, may save far more than its cost by economies effected in construction. On the economic side, there is too often but little attempt, not only to weigh projects as to their need and comparative worth, but also from the standpoint of ability to finance. Contrary to popular impression, there are distinct limits to the funds that can be drawn from the public purse.

Whether or not one holds that there should be some control over public works as a stabilizing factor on employment, the fact remains that advance planning of public works and long-range budgeting are necessary elements of wise governmental economy. They are but the application of the foresight and the common-sense practices of private business, to the business of Government.

On the Engineering Profession, more than on any other group, falls the important duty of guiding and educating the public to the need of orderly planning of public works. It is a highly important part of engineering economics.

In his address on "The Engineering Profession," delivered at the Commencement Day exercises of the Massachusetts Institute of Technology, on June 8, 1937, Gano Dunn, M. Am. Soc. C. E., laid emphasis upon the responsibilities of the engineer in the field of economics. In discussing science and engineering he stated:

> "The essential difference between the scientist and the engineer lies in the economic involvement of the engineer's work. It is in this hot crucible of the economic test that all an engineer does must be tried * * * . Economics is not a physical science. It is a social science, bringing in problems of the human spirit and the behavior of man as man, and it is because the engineer's art deals with dollars and economic relations that he is bound into the great business structure of society in a way that the scientist is not. Being bound into this structure, he must be a man among men. He must be able to make his views prevail. He must be able to persuade and contend. And he must be able to give blows and to take them."

THE CONSTRUCTION INDUSTRY OF THE UNITED STATES

Statistics of the construction industry of the United States have not been available in comprehensive detailed form until recently. The information at hand is that of estimates prepared after long and arduous analysis of statistics of many territorial divisions of the construction field and of many classes of construction. Where these statistics do not cover the entire country estimates must be made of the construction in the territory omitted. A chief source of information is the F. W. Dodge Corporation, of New York, N. Y., which, since 1924, has reported construction contracts awarded in 37 States east of the Rocky Mountains. Another is the volume of building permits issued in more than 800 cities throughout the country, compiled by the United States Department of Labor. Analysis must be made of the construction work done by the many Federal departments, bureaus, and relief and other agencies, supplemented by analysis of construction done by State, county, and municipal agencies. Allowance must be made for construction and maintenance work, by force account labor and not by contract. Duplications must be eliminated. Then, too, it should be recognized that the aggregate totals of contracts awarded and of building permits issued may generally be less than the ultimate cost of the projects which they represent. Innumerable difficulties beset the path of the statistician who seeks to determine the true financial picture of the construction industry.

From its establishment in 1931, the Federal Employment Stabilization Board did notable work in statistical analysis of the national construction industry; this having been undertaken by Corrington Gill, Chief Economist, in co-operation with the Board's executive head, Donald H. Sawyer, M. Am. Soc. C. E. The reader interested in the subject may well consult the writings of Arthur D. Gayer.[2] Estimates of total construction in the United States, based chiefly on the volume of construction materials produced each year, have been prepared by Simon Kuznets, of the National Bureau of Economic Research.[3] The latest publication on this subject that has come to the writer's attention is a *Bulletin* entitled, "The Construction Industry," issued by the Bureau of Foreign and Domestic Commerce of the U. S. Department of Commerce, in April, 1936.

Total Construction, Public and Private.—A comparison of several principal estimates of the total volume of construction in the United States is presented in Table 1(*a*).

* No estimate.

Estimates of the Federal Employment Stabilization Board, as compiled by Gill,[4] are listed in Column (1), Table 1. For the years, 1925 to 1929, values for pipe-line, gas, telegraph, and water-works companies are omitted; but they are included in the years, 1930 to 1932. In Column (2), Table 1, Gayer[5] has corrected the values in Column (1) to include the estimates for pipe-line, gas, telegraph, and water-works construction in 1925 to 1929, by an average ratio, 8.91%, which these items bore to the other construction in 1930 to 1932. Estimates prepared by Gayer, based on data released by the F. W. Dodge Corporation, the Federal Employment Stabilization Board, and the U. S.

[5] *Loc. cit.*, pp. 65, 69, and 70.

Bureau of Public Roads, are given in Column (3).[6] Kuznets (see Column (4), Table 1) bases his estimates mostly on the volume of construction materials produced each year.[3] These estimates are distinctly higher than the others and are believed by the writer to be in excess of actual amounts. The estimates of the Department of Commerce (Column (5), Table 1) are the most recent, and presumably have been presented with previous estimates in mind. It will be noted that in the 5-yr period, 1925 to 1929, inclusive, the total volume of construction, public and private, averaged approximately $12 000 000 000 annually.

Total Construction in Relation to National Income.—The importance of the construction industry in the national economic structure may be gaged by comparing its amount with that of national income. For this purpose estimates of national income produced are given in Table 1(*b*). In the case of national income, as in total construction, authorities differ in their estimates. Comparison of Table 1(*a*) and Table 1(*b*), however, indicates that in the predepression years, 1925 to 1929, inclusive, the total volume of expenditures for construction was roughly one-sixth of the national income. In 1933, however, when construction had reached its lowest level, total construction as estimated by the Department of Commerce (3.5 billion dollars) was only about one-twelfth of the national income produced that year.

Analysis of Estimates of Total Construction.—Beginning with 1925, estimates of total construction in the United States from three sources are available in such detail as to permit a comparative analysis under the classifications of: (*a*) Private construction; (*b*) public utilities (including railroads); and (*c*) public works. Such analysis is given in Table 2. Of the three groups of estimates in Table 2, the first in point of time is that of the Federal Employment Stabilization Board made by Gill. Next followed the estimates of Gayer prepared in 1934 for the National Planning Board and, after some revision, published in 1935 by the National Bureau of Economic Research under the title, "Public Works in Prosperity and Depression." Data for both the Gill and Gayer estimates in Table 2 have been taken from this book. The latest available estimates are those of the Bureau of Foreign and Domestic Commerce of the U. S. Department of Commerce and published in 1936 in its *Bulletin*, "The Construction Industry," from which the data of the third group of estimates in Table 2 are derived. Attention is called particularly to the fact that the estimates in Table 2(*a*) for the years, 1925 to 1929, inclusive, do not include, in the utilities group, expenditures for pipe-line, gas, telegraph, and waterworks construction; hence, for these years, the totals for both utilities and total construction are below their true values. The estimates in Table 2(*b*) and Table 2(*c*) include allowances for construction by these several public utilities in the years named. Beginning with 1930 the construction expenditures of these utilities have been reported.

It will be noted that the public works estimates in Table 2(*b*) are generally higher than those given in Table 2(*a*). From reading the report by Gayer[2] one gains the impression that he makes a good case for the authenticity of his own estimates, and, at the same time, one is impressed by the difficulties and complexities which confront the statistician working in this field. The U. S. Department of Commerce, in its later publication, appears to have favored the estimates by Gill rather than those by Gayer.

PUBLIC WORKS

The distribution of public works expenditures between the Federal Government, the States, and political subdivisions of States, has been investigated by the Federal Employment Stabilization Board and subsequently by the U. S. Department of Commerce. The estimates of these two agencies are in close agreement from 1925 to 1929, after which there is some variation in the item of Federal expenditures. Although in both cases the estimated total volume of public works in each year prior to 1932 is less than that in the Gayer estimates prepared for the National Planning Board (as will be noted from Table 2), the estimates of the Department of Commerce are used herein as the latest and most complete breakdown of expenditures for public works. These data of the distribution of public works expenditures between the Federal Government, States, counties, and cities, for the years, 1925 to 1935, inclusive, are given in Table 3. In this table, Federal aid is included in Federal expenditures and excluded from those of States and their political subdivisions.

TABLE 3.—DISTRIBUTION OF PUBLIC WORKS EXPENDITURES (Estimated* by Department of Commerce; Federal Aid Is Included in Federal Expenditures and Excluded from Other Divisions)

Year	(a) DOLLAR DISTRIBUTION, IN MILLIONS					(b) PERCENTAGE DISTRIBUTION				
	Cities	Counties	States	Federal	Total	Cities	Counties	States	Federal	Total
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)
1925	1 280	780	410	240	2 710	47	29	15	9	100
1926	1 300	680	400	250	2 630	49	26	15	10	100
1927	1 480	880	440	240	3 040	49	29	14	8	100
1928	1 420	830	500	250	3 000	47	28	17	8	100
1929	1 340	560	580	280	2 760	49	20	21	10	100
1930	1 500	710	710	310	3 230	46	22	22	10	100
1931	1 300	330	780	410	2 820	46	12	28	14	100
1932	800	140	550	520	2 010	40	7	27	26	100
1933	400	100	500	590	1 590	25	6	32	37	100
1934	500	130	400	1 100	2 130	23	6	19	52	100
1935	550	130	350	1 000	2 030	27	6	17	50	100

* "The Construction Industry," 1936, Bureau of Foreign and Domestic Commerce, U. S. Dept. of Commerce.

In the pre-depression years, 1925 to 1929, inclusive, the average public works expenditure in each of these four divisions was as follows:

Division	Expenditure	Percentage of total
Cities	$1 364 000 000	48.2
Counties	746 000 000	26.4
States	466 000 000	16.5
Federal	252 000 000	8.9
Total	$2 828 000 000	100.0

Thus, in this pre-depression period, local governmental units accounted for three-quarters of the total expenditures for public works, and the State Governments for one-sixth, whereas the expenditures of the Federal Government were only about 9% of the total. Analysis of Table 3 reveals some striking facts as to what actually happened to the public works program during the depression.

Federal expenditures which, prior to the depression had averaged about 250 million dollars annually, rose steadily during the Hoover Administration and reached 590 million dollars in 1933. The Roosevelt Administration program inaugurated in 1933, increased them to one billion or more in 1934 and 1935. The States themselves expanded their construction activities from 1929 and carried forward enlarged programs until 1933, after which year State expenditures dropped somewhat below the pre-depression average. City and county expenditures, however (which together averaged 2 110 million dollars prior to 1930 and amounted to 2 210 millions in the latter year), dropped sharply to 500 millions, or less than one-quarter of the former values, in 1933, and increased but slightly in the two years following.

Considering the 6-yr depression period, 1930 to 1935, as a whole (6 yr being taken as 1935 is the latest year for which data are available), and contrasting it with the pre-depression period, 1925 to 1929, it is found that, in the aggregate, city and county expenditures were more than 6 billion dollars less than they would have been had the pre-depression average been maintained. On the other hand, the aggregate of State expenditures was nearly half a billion, and of Federal expenditures 2.4 billion, more than the maintained pre-depression figures. The net result is an aggregate shrinkage of more than 3 billion dollars in public works expenditures from 1930 to 1935, inclusive. In other words, contrary to the general impression that these depression years were years of stimulated activity in public works, the facts are that the country's public works program was a full year behind schedule at the end of 1935.

Federal vs. Local Public Works.—A paper entitled "Federal *vs.* Local Public Works," was presented in 1937 by William Stanley Parker,[7] based on the data reproduced in Table 3. Mr. Parker's conclusions as to the "depression relationship" between Federal public works and those of the combined State, county, and city groups (which he classifies, collectively, as "local" public works) are so pertinent that all interested students of the subject will wish to read it at the source.

According to Mr. Parker, the 1929 commitments for "local" public works formed the peak in 1930. The beginning of the slump began to show in 1931, and the decline in local expenditures than continued sharply to a low point in 1933. Federal expenditures, on the other hand, began to increase in 1929; in 1932 they had doubled, and had increased still more in 1933. Quoting Mr. Parker: "These increases represent the effort of the Hoover administration to offset the mounting unemployment in the construction industry." The comparison of the cumulative totals for the 3-yr period, 1931, 1932, and 1933, is as follows:

Decrease in "local" expenditures (below the 1930 peak)	$3 800 000 000
Increase in Federal expenditures (including the 1929 and 1930 increases)	$ 860 000 000

An accumulated shortage of about 3 billion dollars is indicated by the foregoing data, or the equivalent of an entire "normal" year's work. The efforts of the Federal Government are thus seen to be relatively ineffective.

The new Federal relief program was initiated in 1933 and developed in subsequent years. Expenditures on Federal projects were increased, "grants were made to local and state authorities and loans at low interest rates sought further to stimulate local expenditures." At the same time, Mr. Parker states that the Federal Government was spending large sums for relief, a substantial proportion being on minor construction projects which were not included in his basic statistics. Quoting:

> "Federal expenditures on public works, including grants, mounted to $1 100 000 000 in 1934 and to an estimated billion in 1935, four times their 'normal' amount. What happened to local expenditures in these two years? The expenditures of states dropped steadily, from the 1933 total of 500 million to 400 million in 1934 and 350 million in 1935. County expenditures increased about 30 million and cities increased theirs about 150 million, the net result being that in 1934 and 1935, in spite of the urgent need of employment, especi-

---

[7] *The Architectural Record*, May 1937, p. 12.

ally in the construction industry, in spite of the efforts of the Federal government to incite local governments to develop their programs, and in spite of the local help through Federal relief expenditures, the combined expenditures of states, counties and cities for public works remained practically the same through 1934 and '35 as they were in the low peak year of 1933, being only little more than one-third of their 'normal' amount."

Furthermore, Mr. Parker stresses the fact that statistics for 1935 reveal that the total bonded indebtedness of States, counties, cities, and towns was 350 million dollars less than in 1932, indicating "a strange failure of local governments to cooperate with the Federal program which had come to their rescue."

His comparison of cumulative totals for 1934 and 1935, similar to the 3-yr period, 1931, 1932, and 1933, is as follows:

Decrease in local expenditures (1934 and 1935)	$3 780 000 000
Increase in Federal expenditures (1934 and 1935)	1 600 000 000

Comparing the new annual totals in these two categories:

Federal expenditures	$1 000 000 000
All local expenditures	1 000 000 000

and, as a final summary, for the years since 1930:

Cumulative decrease in local expenditures	$7 580 000 000
Cumulative increase in Federal expenditures	2 460 000 000

In other words (to quote Mr. Parker), "for every dollar the Federal government increased its expenditures in order to prime the pump the local governments reduced their expenditures by three dollars, and even after the 1933 relief program developed the local reduction was more than twice the Federal increase."

PLANNING AND CONTROL OF PUBLIC WORKS

Several of the States, notably New Jersey and Idaho in 1915, Pennsylvania in 1917, California in 1921, and Wisconsin in 1923, passed legislation providing for expansion of public works construction as a remedy for unemployment, but these measures either remained inoperative or produced negligible results. A few city and county governments have undertaken to prepare long-term public works programs. Thus far but little has been accomplished in this direction by the States and their political subdivisions.

For a dozen years following the World War, attempts were made repeatedly to secure Federal legislation for the orderly planning and control of Federal public works. These efforts proved fruitless until 1931 when Congress passed legislation creating the Federal Employment Stabilization Board. The purpose of the Act was to provide for "the advance planning and regulated construction of public works, for the stabilization of industry, and for aiding in the prevention of unemployment during periods of business depression."

By the Employment Stabilization Act of 1931 the Federal Government established a policy which, if followed consistently by State and municipal governments throughout a period of years, may not only assist in stabilizing employment, but at the same time should result in wiser and more economical expenditures for public works. An important feature is the requirement that Federal departments and other agencies having charge of construction shall "prepare a six-year advance plan with estimates showing projects allotted to each year," with the further provision that the 6-yr program be kept up to date by annual revision and extension. Thus, the principle of advance planning has been established by law. A second important feature is recognition of the need of co-operation in advance planning between the Federal Government and State and municipal governments if control over public works is to be in any degree effective. The Federal Employment Stabilization Board was directed to watch, constantly, the pulse of the construction industry, to keep the President informed regarding business activity and the trend of employment, and to give warning of the existence or approach of periods of business depression and unemployment so that at such times the President might advise the Congress regarding needed expansion of the public works program.

In the Federal Employment Stabilization Board the theory of planned public works was put into large-scale operation for the first time in the United States. The Board compiled the first reliable data on construction expenditures in the post-war period. Its work was of great assistance to the Public Works Administration in determining the allocation of funds appropriated under the National Industrial Recovery Act of 1933. The latter Act created the Federal Emergency Administration of Public Works which, in turn, set up the National Planning Board as its advisory body. Both these agencies took over some of the functions of the Stabilization Board which then continued to operate as the Federal Employment Stabilization Office of the Department of Commerce.

Basic Principles.—A controlled public works policy is usually looked upon as a flexible policy which will exert some degree of stabilizing effect on changing business cycles—a policy by which public works construction will be retarded to some extent in prosperous periods and expanded to relieve unemployment in periods of depression. The principle of controlled public works has not yet been given a fair trial since what has been done thus far has been done under the pressure of an emergency and without careful advance planning. It has not yet been put into large-scale operation in the United States in prosperous times and the extent to which it may lessen the severity of a depression has not been demonstrated. The recent depression has taught its lessons, however, which may well serve as a guide to future policy. Among them may be noted the following:

(1) Long-range advance planning and budgeting are absolutely indispensable for the success of any plan of controlled public works.

(2) The Federal Government cannot undertake the task alone. The excess of Federal expenditures for public works since 1930 has been nullified and much more than offset by the sharp drop in expenditures by counties and cities. To be successful, State and local governments must do their share. It is a nation-wide problem.

(3) The financial program, or long-range budgeting, is an important element. In prosperous times some cities have wisely followed, to a greater or less extent,

a "pay-as-you-go" policy, paying for capital expenditures out of current income, thus accumulating reserves of borrowing capacity and having strong credit with which to face a depression. This has been true of certain State Governments as well. Recently, the suggestion of creating reserve funds in boom periods to be drawn upon for public works construction in periods of depression has been given publicity. In general, the financing of public works during depressions, especially if construction programs are then to be expanded, may be accomplished in one of two ways; either by drawing upon previously accumulated reserves, or by long-term or short-term borrowing. Of these two methods, borrowing, preferably for short terms, is generally favored. Federal and State credit is usually such that borrowing presents no serious difficulties. This may not be the case with local units on which rigid limits may have been placed as to borrowing capacity. Such restrictions have doubtless accounted, in part, for the sharp drop in city and county public works expenditures since 1930. Long-term budgeting must concern itself with the problem of conserving the borrowing capacity of these local units or of finding means (as has recently been done by legislation in several of the States) whereby restrictive limits on borrowing by local units are raised somewhat during an emergency caused by a depression.

(4) A controlled public works policy should not be looked upon as a means of relieving, directly, unemployment among workers outside the construction industry by giving them employment on construction projects. In any important depression period private construction will surely decline, public utilities may be forced to curtail their construction activities somewhat, and inevitably there will be considerable unemployment among workers normally employed in these branches of the industry. Controlled public works construction, however much it be expanded during a depression, should give direct employment only to those workers within the construction field.

(5) The unemployed must be supported in any event out of public or private funds. The real net cost of public works during a depression, apart from any stimulating effect upon the business cycle, is actually much less than it seems because, in public works, the community gets something in return for its expenditure.

Some may ask, "Can a sufficient volume of genuinely needed public works be found in depression periods to give substantial employment?" The answer is "yes," if construction programs are carefully planned in advance and retarded in periods of prosperity. Roads and bridges are examples of construction suitable for a flexible program.

The construction industry, as a whole (in which, in normal times, expenditures are roughly one-sixth of the national income) is a highly important part of the national economic structure. Public works normally constitute about one-fourth of this industry. Public works alone give primary and secondary employment to a substantial number. In primary employment it has been estimated that normally about 800 000 workers are directly employed in the field, and for every worker directly employed one or two others are employed indirectly in the manufacture and transportation of construction materials. Thus, the normal primary employment due to public works may be, roughly, 2 000 000 wage earners. These workers, in turn, spend a very large proportion of their wages for consumer goods and services thus creating a "secondary" employment in other fields perhaps, roughly, as large again.

If it were possible to maintain the construction industry as a whole at a fairly uniform level, much would be accomplished in "flattening" the business cycle curve and in effecting a marked stabilizing influence on national income. The volume of private construction, however, is not susceptible to public control and is certain to fluctuate widely. The control of public works construction such that its volume remained fairly constant, or was expanded somewhat in depressions, would have appreciable effect in lessening the severity of a depression in the construction industry and, at the same time, would stimulate employment, to some extent, outside that field. If public utilities should join with public works in stabilizing their construction programs, these two (which, together, account for more than one-half of all construction activity of the country, because of the increased primary and secondary employment thus created), would measurably improve the business of the country in depression periods. Such co-operation is not possible at present, however, under existing taxation laws.

Federal Aid in Non-Federal Construction Work

During the recent depression, the Federal Government has made a radical departure from principles to which it had adhered for a century and a half by embarking upon the new policy of lending its credit, and of giving grants outright, to aid the construction of projects which it does not own. That this is an emergency policy, of temporary nature, which will shortly be brought to an end, is generally understood. The precedent having been established, however, undoubtedly there will be an insistent demand for the resumption of this policy when the next severe depression comes. If that is the case, long-range advance planning becomes vitally necessary.

It was in 1932 that the United States Government inaugurated the policy of using its credit to aid borrowing by local governments for their public works. By an Act passed in July of that year, Congress authorized the Reconstruction Finance Corporation to make loans, up to the aggregate amount of $1 500 000 000, to States and their political subdivisions and agencies, and in certain instances to private corporations, for "self-liquidating" construction projects. Although this was the first time that Federal credit had been used in this country for construction of other than Federal public works, the idea was not new. For forty-five years this policy had been at work in England where, through the agency of the Public Works Loans Board, most of the funds for housing and similar projects undertaken by the smaller municipalities had been borrowed from the National Treasury.

This 1932 Act was a demonstration of the growing belief in the value of expanded public works programs as a means of affording unemployment relief. Because of the stipulation of the Act that loans by the Reconstruction Finance Corporation must be restricted to revenue-producing or "self-liquidating" projects, and of the policy of the RFC in charging relatively high interest rates, authorizations were made very slowly and disbursements more slowly still. Only a minute fraction of the one and one-half billion dollars authorized had been put to work for the relief of unemployment before this Act was superseded by that of 1933.

The National Industrial Recovery Act of June, 1933, appropriated $3 300 000 000 for public works; authorized grants as well as loans to States, municipalities, and other public bodies; created the Federal Emergency Administration of Public Works (PWA) to administer the Act; and required the PWA to "prepare a comprehensive program of public works," Federal, State, and local.

Engineers throughout the country, perhaps better than any other group, realize the chaotic conditions as regards public works planning precipitated by the 1933 Act. In the feverish haste to put the vast Federal appropriation to work for the relief of unemployment there was no time to prepare orderly programs or even adequate preliminary plans. Almost over night as it were, engineers everywhere were called upon to prepare applications for public works projects in the form required by the PWA, which all too often involved guesses as to site conditions, estimates which were scarcely more than guesses of probable cost, and plans which were the merest sketches. There was no time for economic planning as to the need and comparative worth of various projects. Thus, at the outset and for a long time after the 1933 Act became operative, orderly planning was not possible and scant attention was paid to a "comprehensive program of public works."

Under this Act, however, the Administration committed itself to the principle that orderly planning and control was necessary to secure efficient and socially desirable expenditure of public monies in the public works field. The Act contained no statement concerning the possible utilization of public works as a stabilizing factor, but the prominence, in the Act, of the stipulation regarding the formulation of a comprehensive, nation-wide program seemed to imply that in the future such a program could be utilized toward that end.

Within the framework of its initial organization the PWA set up in 1933 the National Planning Board, an advisory body, to which was assigned the preparation of the comprehensive program required by the 1933 Act. The functions of the National Planning Board, as stated, were to engage in research concerning the potential development of public works in relation to social and economic needs and to draw up a comprehensive plan for regional areas in co-operation with National, State, and local agencies. As for planning agencies throughout the country, in the summer of 1933 there existed at the top of the pyramid the newly created National Planning Board and at its base about 700 municipal planning boards in the principal cities and in certain of the larger towns. Between the top and the base, State and regional planning agencies were almost wholly non-existent.

In that year the President addressed communiciations to the Governors of the several States urging the creation of State planning boards to assist in the orderly planning and programming of public works in their respective States, particularly as an aid to the PWA in the allotment of grants and loans. Applicants to the PWA for such Federal aid were required to state whether the projects in question formed parts of comprehensive plans and had received the approval of State and local planning agencies.

New Hampshire was the first State to comply with the President's request and immediately Governor Winant appointed an unofficial State Planning Board. The example set by New Hampshire was followed by a large proportion of the States. In most cases these boards were necessarily unofficial bodies, at first, created by executive order so as to avoid the delay of waiting for State legislation. At present (1937) there are State Planning Boards in forty-five of the forty-eight States, and of these, thirty-six Boards are now permanent official bodies established by legislative act.

The National Planning Board has fostered the creation of interstate regional planning commissions when groups of States have problems of special regional interest. The New England and Pacific Northwest Regional Planning Commissions are examples of such bodies.

The experience of the four years, 1933 to 1937, in attempting to promote useful and needed public works projects as a part of the Federal aid program for unemployment relief, has demonstrated conclusively to those concerned with these public works, if not to the public generally, both the need of advance planning and that of fitting public works plans into a logical pattern. If any lesson is to be learned from the experience of the last few years, it is that public works should no longer be planned and constructed in a "hit-or-miss" fashion but that henceforth, the need for them should be studied with proper foresight. The Roosevelt Administration deserves commendation for its stand regarding the necessity for advance planning, and for its efforts toward co-ordinating public works projects, Federal, State, and local, into something like an orderly program which will promote wise and economical use of public funds in this field.

ADVANCE PLANNING

Whatever differences of opinion may exist as to the wisdom of some control over public works as a stabilizing factor on employment, all must agree that advance planning and long-range budgeting are common-sense business practices. They are absolutely essential in private business. They are practiced likewise by leading public utilities of which the nation-wide telephone company is a notable example. It is in the business of Government, particularly in the case of public works, that the necessity for foresight and economy is all too often ignored.

Advance physical planning of public works requires some modification of the practices usually obtaining in governmental departments, particularly those of the State and local governments. Rarely do these departments take a long-range view and give thorough and detailed study to their requirements for some years in advance. Usually, the departments themselves are not primarily at fault. Mistaken governmental economy in far too many cases allows such meager appropriations for technical service that thorough engineering investigation of public works projects well in advance of their authorization is not possible. Frequently such projects are authorized on hastily prepared plans and estimates, without careful advance study based on adequate knowledge of conditions to be met. Only when funds for construction become available is it possible, in many cases, to start a general engineering investigation and by that time pressure to get construction "under way" leaves little time for thorough engineering planning.

The departments themselves may often be subject to criticism, however, for failure to impress upon appropriating agencies the wisdom and ultimate economy of adequate appropriations for engineering service which will provide a competent organization sufficient to handle current work and, at the same time, give proper consideration to work foreseen as needed in the future. Too many governmental departments live on a "hand-to-mouth" or day-by-day policy. At most, it is from administration to administration. A new governor or a mayor is elected; new department heads are appointed. There is usually a sincere intention on the part of the Chief Executive to administer the affairs of the State or city wisely and well, but no carefully prepared and formally accepted long-term program or pattern awaits his coming. There is all too often, therefore, a perfectly understandable human tendency to discount the efforts, the efficiency, and perhaps even the sincerity, of earlier administrations; to abandon projects already begun; to divert—with consequent loss—millions of dollars from one channel of public activity to another; and to venture into new and unexplored fields without the benefit of proper advance technical planning. In the absence of advance planning, under the present system of Government, and in the light of human nature, this cannot be otherwise. No one can change human nature. Americans do not want to depart from their democracy in Government; they can and should prepare well in advance, and within reason should adhere to, carefully considered programs for public works activities.

The public thinks engineering inconsequential and something that can be done in a hurry when required. There is great need of public education as to the importance of engineering investigation before proceeding with construction. The serious lack of adequate advance physical planning by departments of State and local governments has been glaringly evident in connection with the current program of Federal aid in non-Federal public works.

Advance financial planning or long-range budgeting of the public works program is of equal importance with advance physical planning. A few American cities have already led the way in preparing long-time bond or financial programs for public improvements. If the example which they have set were general practice in State and local governments, greater economy and more uniformity in expenditure would result. The danger of rushing ahead with poorly considered and less necessary projects, and with projects which the community can ill afford, would be largely reduced.

Timing of public improvements is an important part of advance planning. Proper timing will result if there is co-ordination of advance physical planning and advance financial planning; in fact, all three are factors of a single problem. Timing so as to retard public works programs somewhat in periods of prosperity and to advance them in depressions is necessary if public works are to be utilized as one phase of an economic stabilization program.

Co-ordinated, long-range public works programs are made up of many diverse elements. They are desirable and economically necessary for city, county, State, and Federal Governments. How then is proper co-ordination to be secured? It is not a matter that can be handled adequately by individual governmental departments alone. Each department, it is true, is best qualified to forecast and plan for the needs of its own particular field, but its vision is limited, it may know little or nothing of the needs of another department, it is naturally biased to a greater or less extent by its conception of the importance of its own problems, and it is not an impartial judge. In no governmental unit, State or local, will a well-considered and well-co-ordinated long-range program of public improvements, best suited to the needs of that unit as a whole and within its capacity to finance, result from a round-table discussion between representatives of the departments directly concerned with carrying out these improvements. A broader, more detached, and more impartial viewpoint is needed.

Co-ordination is planning in its broadest terms. It can well be secured through some form of non-political planning agency, acting independently of other departments of the Government, free from all administrative responsibility for the construction of projects, and one in which a substantial proportion of its members, at least, shall be appointed in rotation for fairly long terms in order to secure continuity of policy. Such planning agency should work in closest co-operation and harmony with other governmental departments responsible for public improvements and for the Government's financial administration. Heads of certain of these departments may well be members, *ex-officio*, of the central planning agency in order to secure closer co-operation and a better understanding of public works problems and their relation to the Government's financial policy. It would seem best, however, that the majority of the members of the planning body should be free from other governmental duties and responsibilities in order that they may exercise unbiased judgment. Such membership presents an opportunity for engineers, architects, planners, economists, business men, and civic leaders of highest standing to render service of great value to their community.

If the challenge is fairly met, and public officials work in co-operation with the planning group, then an orderly progress may be expected in promoting a long-term program of public works, in establishing efficiency in administration, and in effecting real economy in government.

INFLUENCE OF PUBLIC OPINION

BY DANIEL W. MEAD,[8] PAST-PRESIDENT AND HON. M. AM. SOC. C. E.

SYNOPSIS

A well informed public can and will raise such objection to projects which they know to be unsound that no Federal, State, or Municipal Administration will dare to undertake such projects.

Public works are, in general, so complicated as to be little understood by the general public. In recent years and in the past, many uneconomical public works have been undertaken, for reasons of political expediency, and have gone unchanged because the public has not understood their unsound character. This lack of understanding by the public is largely due to the fact that the Government seldom furnishes the information necessary for a basis of sound judgment, but misleads and misinforms the public by extravagant statements and propaganda favorable to such projects.

Engineers, from their training and experience, can and should study these projects and inform the public, in simple language that can be readily understood, the facts concerning such projects that will give the best possible knowledge from which the economic feasibility and desirability of such ventures may be judged. Some of the Government projects of the past, present, and probable future, are discussed briefly, herein, and these objectionable features pointed out.

THE RECORD OF GOVERNMENT IN BUSINESS

There is no profession more affected by depressions than that of Engineering. In consequence, there are no men who are more interested, and none better qualified to assist, in the re-establishment of normal conditions than engineers.

After seven years of waiting (1930 to 1937) which includes five years of Federal Administration experiments, the depression is still present. Whether partial recovery, as far as recovery has occurred, is due to, or in spite of, administrative activities will be a moot question for years to come. There are still under consideration many suggestions for further radical changes in social and business relations.

The engineers of the United States will do less than their duty if they hesitate to discuss these matters frankly, honestly, intelligently, and fearlessly, and bring to bear on the solution of these vital problems the best thoughts of their profession.

Many ill-conceived and unwarranted public and semi-public works have been undertaken by the Federal Administration since the beginning of the depression. The more these ill-considered and extravagant projects are discussed and their defects made plain to the public, the more likely it is that they will be prevented in the future by the development of a sound public opinion. To the mind of the writer, a well informed public can raise such objections to unsound projects that no administration—municipal, State, or Federal—will dare attempt projects that are not based on thorough investigation, sound judgment, and sound economies.

---

[8] Prof. Emeritus, Hydr. and San. Eng., Univ. of Wisconsin; Cons. Engr., Madison, Wis.

The writer believes that there are many matters at the present time that are even more important to the engineer than the very important matter of ill-advised public works. On account of the introduction of labor-saving machinery and other mechanical devices that have saved labor, increased production, and reduced cost, the Administration has charged the Engineering Profession with the production of unemployment. The facts are diametrically opposite to this theory.

The National Resources Committee reports:[9]

> "* * * in the period from 1870 to 1930, the population of the country multiplied by three while the number gainfully employed multiplied by nearly four. * * * The eighteen major industries of today which employ directly and indirectly about 25 per cent of those gainfully employed in this country were absolutely unknown in 1870. While mechanical power has been instrumental in separating the worker from his tools and agriculture from industry, it has definitely created more callings and more employment than it eliminated."

The Administration has also urged the engineering schools to teach their students to consider not only the design and construction of engineering works but also to study and determine their ultimate effects on society.

Can the Administration believe that the recent construction of vast public works, many of which will compete with projects financed through the sale of securities to the public under the supervision of the various State commissions, is fair to such investors, or that the construction of such works will effect recovery, or be a real benefit to the nation? Are not all honest investors in the securities of public utilities entitled to the consideration of the Administration in the planning of public benefits to the citizens of the United States? This question has been raised frequently but the writer has heard no answer.

The Administration's suggestion for careful consideration of the effects of improvements would have been received more sympathetically if the plans for the construction of these great public works undertaken for the alleged purpose of recovery, could stand sound economic analysis.

The entrance of Government into business is being carried so far by the present Administration that it seems to threaten the ultimate socialization of business and industry and the regimentation of all professional men and workers into Government service.

The record of Government in industry, whenever it has been tried, is not a satisfactory one and warrants no further extension of Government into business. The fiascos of the Government control of the railroads during the World War, of the Government-owned railroad in Alaska, the Government ownership of railroads in Canada, seem to have little weight on public or political opinion.

---

[9] "Report on Technological Trends and National Policy," June, 1937, p. 254.

The economical records of Federal irrigation projects since 1902 and of the Inland Waterways Corporation since its organization, are thoroughly unsatisfactory. The recent records of the Resettlement Administration and of the Federal Housing Projects are still later exhibits of Federal economic ideas. Can the public and its representatives in Congress learn nothing from experience? or is the trouble due to lack of information? The unfortunate results of these disastrous experiments should be brought to the attention of the public so that they will realize the danger of further experimentation in Government ownership and operation.

An immediate danger that confronts the nation is the further entrance of the Government into the hydro-electric power field. Already the Government is committed to vast expenditure for power development, partly by Acts of Congress, but largely by administration orders. Among such ventures may be named the Tennessee Valley Authority (TVA) involving an expenditure of about a half billion dollars, the Grand Coulee Project which will involve a similar sum, and diverse other Federal projects, including the Passamaquoddy Project, now sleeping, but not forgotten.

The bill before Congress (S. 2555), if it becomes a law, will divide the United States into seven districts, in each of which an authority will be established, essentially similar to the TVA. This will practically place all future hydraulic power development under Federal ownership and operation. It will probably involve the Government in the installation and operation of steam or other auxiliary power plants as in the case of the original Muscle Shoals Project. It may also involve not only Federal navigation and flood protection, but other industries, and ultimately may eliminate local, State, and probably all private industries on a theory of "unified" developments.

It seems to the writer that this bill, if passed, and these policies if continued, will involve "Federal engineering," "Federal domination," and will prove a serious detriment to the future, of not only the Engineering Profession, but of all other professions, trades, and industries.

The writer is opposed to these policies as they involve a direct attack on the liberty of the American people, on individual freedom, and on industrial and professional independence.

DESTRUCTION OF PRIVATE PROPERTY BY GOVERNMENT OWNERSHIP

In the early development of the United States water transportation and water power had a great influence on settlement, and on community development. The eastern seaboard was the section of the country first available to settlement, and local water powers first became the centers of industrial development. The extension of settlement developed, normally and naturally, along the navigable waters. In early days, and quite up to the time of the Civil War, traffic was largely water-borne. Many of the early canals and the early river improvements, even while in themselves largely unprofitable, were warranted by the development of the country which resulted therefrom. As the ox-team and the canal-boat were displaced by the railroad and other more rapid means of transportation, internal navigation on rivers and canals has gradually assumed less and less importance; yet the tradition of the great value of internal navigation has caused the Federal Government to waste hundreds of millions of dollars on navigation projects, such as the Fort Peck Reservoir and the 9-ft channel in the Upper Mississippi River, of little present or prospective economic value.

In the same way the early use of water power has given it a value in the public mind, and more especially to the politician, which in many cases it does not possess. The fact that flowing water is "energy going to waste" is overemphasized and the false value attributed to water power is causing the Federal Government to undertake, and to encourage others to undertake, many developments that are entirely unwarranted, and some of which will probably be utter failures. Such success as is attained will be largely at the expense of private investments already made and will probably involve very great losses to many investors. It required many and severe losses in investments to prove the necessity of limiting competition in the matter of public utilities. In the past, competition was permitted which encouraged unintelligent expenditures and which resulted in heavy losses to competitors, and in entirely unsatisfactory and unduly expensive public service. Every loss to an individual is a loss to the nation. The destruction of private property makes the entire country poorer. It was only after much unfortunate experience that competition was eliminated and regulation substituted with much more satisfactory results.

The Administration, however, has again initiated the uneconomic principle of unrestricted competition, not only by the duplication of plants but also by paralleling transmission lines. Private enterprises suffer in competition with Government ownership because of the unfair advantages the latter has over the former. With capital furnished from taxation and not directly charged against the development, and by omission of taxes, certain Government projects can be made to appear successful and can destroy any private competition.

Indeed many private competitors are being taxed to effect their own destruction. "The right to tax is the right to destroy." The writer believes that intelligent public opinion is in favor of a "square deal" and the securing of satisfactory public service at reasonable prices through intelligent regulation and without uneconomical or unfair Government competition. If Government ownership and operation is other than politically desirable, it should be introduced in a frank, honest, and honorable way.

GOVERNMENT FUNCTION IN BUSINESS RECESSIONS AND RECOVERY

Depressions are not uncommon in this or other countries. Many now living will recall some or all of the depressions of 1884, 1893, 1907, and 1921; and the depressions of 1817, 1827, 1837, 1847, 1858, and 1873 are matters of history.

In all previous depressions, the responsibility for recovery has been met largely by the business interests of the country, and recovery has been brought about within a reasonable length of time. The present is the first time that the Federal Administration has assumed the responsibility of recovery.

Administrative action is apparently based on the theory that recovery can be effected only by an entire re-adjustment of business and social relations under strict Federal laws and regulations, and that radical changes are necessary in the basic principles of the American Government, which principles have been highly satisfactory during the last one hundred and fifty years.

Long experience has demonstrated that legislation passed to improve social conditions frequently results in effects quite different from what were expected, and usually must repeatedly be changed and modified to accomplish the results desired even approximately. It seems strange, therefore, that apparently both public and political opinions still adhere to the belief that almost any evil in social or business relations can be remedied immediately by "passing a law." Satisfactory social changes are not accomplished so simply.

In spite of the warnings of experience, the Federal Government has been, and still is, passing radical legislation which can but delay recovery on account of the experimental character of the changes involved and the effect of the uncertainties on public confidence. C. F. Roos, Director of Research of the defunct National Recovery Administration (NRA), stated:

> "* * * although I was invited to join the NRA staff as a friend of the new administration and went to my work with a sympathetic attitude, the data accumulated by our research workers forced upon me the conviction that their type of legislation was a mistake. * * * These studies also show that NRA regulations of hours and wages kept business recovery at a standstill for a two year period."

To care for the unemployed, the Public Works Administration (PWA) was organized and has been the most satisfactory and effective activity attempted by the Administration. It has been, as far as it has been allowed to act, fully as satisfactory as could be expected from any Federal emergency agency. Securities issued by various municipal organizations and not otherwise salable under the conditions of the depression, were taken by the Federal Government, and the avails plus a bonus of 30% (which was afterward increased to 45%) were furnished under Federal supervision of projects.

The writer believes that the principle of Federal grants was a serious mistake. Such grants must ultimately be paid by the taxpayers of the entire nation and could not be made with any degree of equality throughout the country. The grant encourages extravagance in local public works, not immediately necessary, in order to obtain the subsidy which the locality must pay in part in any event. Works of real necessity would have been assured by Government loans at low rates, which the community benefited would ultimately have been obliged to pay. Such a plan, therefore, would not have resulted in an unfair distribution of benefits and taxes.

The increase in grant from 30% to 45% has resulted in some communities receiving 50% greater grants than other adjoining communities that were more prompt in the efforts to adopt relief work. Other communities that had not sufficient influence to secure such grants were independent enough to pay the entire costs for needed works and will now, by the payment of taxes, unfairly be obliged to help other communities that received Federal assistance.

In the main, the PWA seems to have been well organized and the works well selected and well conducted, when all conditions are considered. In some cases, however, monies were appropriated for the purpose of constructing municipal plants where cities were already served by private corporations.

Power districts were also organized and subsidized in locations adequately served at reasonable rates. In some cases not only were the projects subsidized by furnishing 45% of the cost, but the Administration purchased the bonds issued as no other market for such bonds was available, and thus such questionable projects have been or are being constructed at Federal risk with no other responsible organization behind them.

In all these power projects subsidized by the PWA as well as in the case of larger projects which have been undertaken by the Administration directly, private power companies already in the field have been seriously threatened, and thousands of stockholders who through their faith in fair treatment by Federal and State utility commissions have invested their limited savings in such enterprises, are threatened with serious loss through Federal competition, often in a market already adequately supplied with electrical facilities.

To start the work of the PWA in an intelligent and effective manner required time and, temporarily at least, it did not respond to the immediate need for work relief. To meet this need the Civil Works Administration (CWA) was organized. Under this Administration the municipalities paid in part for materials used, and the remainder of the cost and labor costs were met by the Federal subsidies. This work was not let by contract but was done by day work under Federal supervision. Thus began the diversion of work from its legitimate channels of the construction industry, and the spending of Federal funds for more or less unnecessary and questionable projects.

The PWA was somewhat free from political and local influence, and most projects undertaken were valuable and worth while. The men employed were largely, if not entirely, from the relief rolls, but they were required to perform a proper amount of work for the time spent and the pay received. Under the CWA the work frequently was performed under inexperienced supervision, and was done, in general, at a cost greatly in excess of what could have been paid under the corresponding industry. Even where other work was available, the men generally refused to accept private service which frequently involved less pay for more work as well as the loss of their positions on the relief rolls. Then, too, the selection of projects was far more susceptible to political and local influence, and the insistence of States and municipalities that they should receive their share of Federal funds, often regardless of the necessity or desirability of the work to be done. In this way, Federal funds could be spread more uniformly over the country, meeting more readily the necessity of local employment but without much regard to the real necessity or desirability of the work to be done.

The CWA was succeeded by the Federal Emergency Relief Administration (FERA) and, later, by the Works Progress Administration (WPA) by means of which relief was widespread and many questionable projects were undertaken, often at an enormously large expense. In this manner, billions of dollars were diverted from the construction industry on the revival of which full recovery and the permanent reduction of unemployment so largely depend.

The first relief appropriation of 1933 was for $3 300 000 000. It was commonly expected that all this money would be spent on a great public works program that would revive the construction industry and furnish needed public works as well as needed employment; but about 25% of this sum or approximately $825 000 000 was used for CWA and the other day-labor agencies. Of the still greater appropriation of 1934 of $4 880 000 000, about $2 500 000 000 was spent by day-labor agencies; and of the 1936 appropriation, about $2 200 000 000 went for day labor. In the last appropriation of $1 500 000 000, it is understood this will largely be spent in the same manner. Thus, the Government apparently has spent and will spend for day-labor enterprises about $7 000 000 000 to the great detriment of the construction industry which under normal conditions and when running at normal rates would employ, in addition to the number now engaged in construction work, an additional force fully equal to the number now on the relief rolls. To the writer it seems doubtful whether the Government has accomplished, by its day's-work program, 20% of the volume of the really valuable work which could have been accomplished had it been done under the PWA and by the construction industry.

Although every right-thinking man must recognize the desirability and the necessity of aiding the needy and taking care of the afflicted, few will agree with Harry L. Hopkins, Administrator, Works Progress Administration, that it is desirable to give the recipients of Government charity a "dignified status" and thus augment the feeling now all too prevalent among those who have received Government aid that the Government owes them a living and that it is a rank imposition that they be required to work at all for what they receive.

Although much has been said concerning intelligent planning and careful consideration of the ultimate results of engineering developments, it is evident that the public works program under construction, so far as its economic aspects are concerned, is the result, not of sound study and thorough investigation, but either of political expedience or irrational inspiration. It seems to be assumed that the ordinary intellect cannot hope to understand the objectives but must be impressed and satisfied by the fact that these projects are the grandest and greatest that the world has ever seen. The fact that some of them are the greatest mistakes that any Government has ever undertaken since the building of the Pyramids, and about as useful, may dawn slowly on the public mind, unless public opinion can be enlightened and freed from false propaganda and political misinformation.

During the decade in which the United States entered the World War many unfortunate enterprises were undertaken. The building of hundreds of ships that were never used; the construction of the Wilson Dam, of an auxiliary steam plant, and of nitrate plants that never were able to function; and the taking over and mismanagement of the railways—all are examples of Government failures which cost the country unnecessary billions of dollars and which should have served as a warning to the people of the necessity of greater intelligence in Congress and of limitations in the authority of the Executive so that vast public expenditures should be based only upon thorough investigation, careful consideration, and intelligent action.

It must be recognized, of course, that emergencies of war and depressions entail conditions which warp the judgment and which confuse intelligent thinking; that under such conditions the people of the nation seem always ready to follow a leader who has positive ideas and who can express those ideas in a manner that seems to make them rational. The idea seems to prevail that not knowing what to do, people should do something, regardless of consequences. The mistakes of the past have left a heritage of evil. The Shipping Board long added an annual deficit to the burden of the taxpayer, and the Wilson Dam and Power Plant furnished the basic excuse for the establishment of the Tennessee Valley Authority.

GOVERNMENT INTERFERENCE AS A PERMANENT POLICY

Power.—The Tennessee Valley Authority is an undertaking of the Federal Government of an idealistic "unified" development of the valley of the Tennessee River for navigation, flood relief, power development, and various altruistic ideals. Power development as an objective is not a legal function of the Federal Government. It can be undertaken only if incidental to navigation. Power development is undoubtedly the primary objective of the TVA. It is also to constitute a "yardstick" for measuring the cost of generating power for comparison with privately owned power utilities.

The TVA is an interesting project which would not be warranted at Federal expense during prosperous times on account of its purely local character and benefits. Under conditions of the depression, and as an aid to national recovery, it is utterly ill-advised and unwarranted, except as a political gesture of undertaking something big and novel under the excuse of aiding recovery. Like most of the Federal works now in progress, exact and detailed information concerning this project is impossible to obtain, and its detailed ultimate objectives are probably as indefinite in the minds of the Administration as they are to the taxpayers.

As a "yardstick" for measuring the cost of power, this and other Federal hydro-electric power projects are complicated by the fact that "navigation," "flood protection," and other "objectives" are also involved, and that both first cost and cost of development, operation, and maintenance must be assigned to these different objectives. Can it be hoped that the TVA or other Federal Authorities, the leaders of which are responsible for the success of these power projects, will be able to assign fair and equitable parts of the great investments to each of the so-called objectives of the projects, or will power unfairly be found to be a mere by-product of navigation and flood protection?

Arthur E. Morgan, M. Am. Soc. C. E., Chairman of the Tennessee Valley Authority, stated:[10]

> "In case public power is used as a 'yardstick' or as a measure of what the private power industry should charge for its services, then it is imperative that records and accounts be honest and fair and open and that there be no hidden element of subsidy. The very fundamental element of such comparison is honesty, fairness, and openness in measurement. Take away those characteristics and the supposed comparison may becloud the issue rather than clarify it."

All fair-minded engineers will certainly agree with the foregoing specifications for a Federal "yardstick"; but it is fair to ask how it is to be established in practise.

---

[10] "Public Ownership of Power," by Arthur E. Morgan, *Atlantic Monthly*, September, 1937, p. 342.

On account of the absence of exact data, the TVA project is very difficult to analyze. The best information the writer has been able to obtain is the testimony before the House Appropriations Committee.[11] At this hearing the inquiries of the members of the Committee brought out certain estimates which, so far as the writer is aware, are otherwise unavailable.

The pertinent data given in this evidence are as follows:

Continuous capacity of integrated system, in kilowatts		666 000
Average annual power output, in kilowatt-hours		5 780 000 000
Estimated annual income		$23 120 000
Less annual cost of power	$12 200 000	
Less other expenses	1 170 000	13 370 000
Net revenue		$ 9 750 000
Estimated cost of dams, locks, and reservoirs		$343 700 000
Cost of power-house and equipment		135 450 000
Total estimate for navigation, floods, and power		$479 150 000

In these estimates no allowance is made for interest during construction or for carrying charges while the market is being developed. An estimate of $20 000 000 for contingencies is also omitted as possibly unnecessary (a deficiency appropriation from the Federal Treasury always can be anticipated).

All these expenses are just as much a part of the actual cost of a power plant development, Federal or private, as the cost of buildings or machinery. Taxes during the development period can be ignored in this case, because, in lieu of taxes, Congress has provided that the States shall receive 5% of the gross income—no sales, no taxes; a very generous provision for the TVA.

Based on the estimated income the TVA finds it can pay the entire cost of the project in fifty years, without interest. Interest, however, is as real an expense as capital cost, cost of operation, or cost of maintenance. The estimated net return (without interest), even if it could ever be realized, will not pay interest on any reasonable basis even on the fair cost of the power project alone.

Even if the TVA estimates are correct, the real net income will be negative and the actual cost of this project to the taxpayer will probably be two or more times the total estimated cost before the Federal bonds, issued to meet the cost of this project, are paid.

It is assumed for this analysis that the estimates of continuous power are correct. Such estimates are of necessity always doubtful on account of great variations in annual stream flow, and in this case, are still more doubtful, on account of necessary regulations for navigation and flood control. It should also be noted that the annual output is based on the daily use of the continuous capacity for 365 days per yr.

---

[11] First Deficiency Appropriations Bill, March, 1936.

It has been assumed in one critical article written on this subject,[12] that, on account of navigation and the necessary load factor (which can only approximate 50%), not more than one-half this power will be available. The writer believes, however, that with the proposed installation of machinery contemplated it may be possible to generate the full daily output of kilowatt-hours within 24 hr at any reasonable load factor without serious effect on navigation. The effect of systematic efforts for flood control will probably be more serious. The income estimate is calculated on the basis of 4 mills per kw-hr on 100% of the estimated continuous capacity.

From the same source of information the wholesale rates established by the TVA on October 22, 1934, are:

Demand charge, in dollars per kilowatt	0.90
First 100 000 kw-hr, in mills	4
Next 200 000 kw-hr, in mills	3
Next 700 000 kw-hr, in mills	2.5
All more than 1 000 000 kw-hr, in mills	2.0

From these rates it is evident that the annual returns, if and when markets are found for the entire output, cannot average as much as 3 mills per kw-hr and that the returns, therefore, would be more than $5 780 000 less than estimated by the Authority. On this basis the project would require about 125 yr, without interest, to pay for itself. (Press dispatches of August 20, 1937, state that a chemical company has contracted with TVA for 12 000 kw of "firm power" at 2.74 mills per kw-hr and 12 000 kw of "run-of-river power," at 2.27 mills per kw-hr.)

The estimated output is based on continuous efficiencies of more than 80%, which is scarcely possible to obtain under all conditions of head and load. There are other losses due to plant use, transmission losses, transformer losses, and losses due to regulation for navigation and flood prevention. Basing his judgment on a somewhat extended experience the writer believes that if, with a complete market, the Authority realizes 80% of this estimate, it will be accomplishing more than should normally be expected.

The writer recognizes that there is available, in addition to the firm power estimate, a large block of irregular seasonal power that will be available during periods of more than average flow, which the TVA calls "run-of-river power," and which is more commonly termed "dump power." He is also aware that contracts have already been made to supply a considerable quantity of such power. This power can be made firm where auxiliary steam power is installed. No such auxiliary power is proposed by the TVA at present. Whether or not this power project can be made to pay on a fictitious cost estimate is of little moment. The real factor of importance is that the TVA seems to be deliberately attempting to "becloud the issue" and to set up a "yardstick" that is clearly dishonest instead of "honest, fair, and open."

---

[12] "Black and White Coal," by C. W. Kellogg, *Bulletin*, Edison Electric Inst., May, 1937, p. 163.

In an attempt to show honesty of purpose the cost of power is estimated on the following basis which on its face would seem to be fair: Interest, 3.5%; depreciation, 3%; taxes, 1%; operation, 1.5%; the total being 9% of the cost of power development. The estimate of power house and equipment ($135 450 000 at 9%) equals $12 191 500, which is essentially the same as the annual cost of power previously quoted. This shows conclusively that the cost of the power "yardstick" is estimated at $135 450 000, and does not include any part of the cost of dams and reservoirs. Under such conditions, are these estimates of cost, income, and profits, free from "hidden elements of subsidy"?

The system of high dams is believed to have been built almost exclusively on account of power development, and any honest estimate of the cost of such development should include a large portion of this cost.

The Army Engineers have estimated[13] the average seasonal flood loss in the Tennessee Valley and its tributaries ($1 784 061). What reasonable sum should be expended to prevent this annual flood loss? A fund of about $51 000 000, if set aside at 3.5%, would pay such annual flood damage. The works proposed, however, will not furnish 100% flood protection. Chattanooga, Tenn.,[14] will have to expend $15 000 000 to secure effective relief; and probably other localities may require extensive local works. In any event, an expenditure of $36 000 000 would seem to be about the limit for this purpose, although indirect damages might warrant some additional expense.

The Army Engineers have estimated[15] the cost of navigation works with low locks and dams at $74 709 000. Although the writer doubts the economic desirability of this investment, he agrees that the higher dams will possibly improve navigation facilities and that an increase to, say, $90 000 000 for this purpose might be warranted.

The estimate of cost for the eleven dams and power plants (as of March, 1936) was $479 150 000; the difference in cost between this sum and a fair estimate for navigation and flood protection will indicate the real cost of power development:

Total estimated cost		$479 150 000
Cost of navigation	$ 90 000 000	
Cost for flood protection	36 000 000	
	$126 000 000	126 000 000
Total cost of power installations		$353 150 000

This is more than 2.5 times the estimate of the Authority, and to it should be added interest during construction, carrying charges during development of the power market, taxes (which would be paid by a private company), and presumably cost of transmission, etc.

As a "yardstick" the writer believes that "the supposed comparison may becloud the issue rather than clarify it." It is quite evident that power, the real primary object of these Government ventures, is to be regarded financially by the Administration as a by-product of "navigation" and "flood protection."

[13] H. R. Doc. No. 328, 71st Cong., 2d Session, p. 730 *et seq.*

[14] "Flood Control at Chattanooga, Tenn.," by E. L. Chandler, *Civil Engineering*, June, 1937, p. 405 *et seq.*

[15] H. R. Doc. No. 328, 71st Cong., 2d Session, p. 5.

The Chairman of the TVA has expressed the opinion[16] that the project is worth all it will cost for navigation and flood protection alone; also that the value of the flood-protection feature will be worth $100 000 000 to flood protection on the Lower Mississippi River. As to the first opinion, it is so extreme that it seems useless to discuss it. As to flood protection value, the writer understands that one primary objective of the TVA is flood protection in the Tennessee Valley. This may or may not co-ordinate with the interest of flood protection on the Mississippi River. The Miami District of Ohio, with automatic reservoir discharge, adds to the floods in the Ohio River about as often as it reduces such floods, depending on the direction of movement, and the length and intensity of storms. Can the TVA accomplish better results?

On the unwarranted basis of the TVA estimates, it is apparent that it estimates the cost of power at about 2.11 mills per kw-hr. On a more reasonable basis of cost of the plants and of the power that can be sold, the probable cost will be from 5 to 7 mills per kw-hr.

Steam power can certainly be generated in the Tennessee Valley for not to exceed 4 mills per kw-hr. As about 65% of the cost of coal is due to labor, it would seem that if recovery was the true purpose of these power developments it would be of greater advantage to use steam power at a much less capital cost as well as a greatly reduced operating expense.

That the power to be generated by this development will never warrant the great expense involved, is further indicated by the findings of the National Resources Committee, which, in its report[17] to the President on June 18, 1937, states that "the high efficiency and the low fixed charges now possible in large fuel burning plants, places hydro-electric developments at a disadvantage in most sections of the United States if low power cost is the objective."[18] (By a majority vote the Tennessee Power Commission has granted permission for the construction of a $2 000 000 steam generating plant in Nashville.)

If there is any honest and intelligent defense for the expenditure of approximately half a billion dollars which is apparently now being largely wasted in the Tennessee Valley, it should certainly be made manifest. This is especially true if the Administration ever expects to secure the backing of public opinion for repeating this seemingly irrational experiment in six other sections of the country.

It seems apparent that the TVA is only slightly less absurd than the Passamaquoddy Project which, however, it greatly exceeds in cost. It is quite equal to the Grand Coulee Project by which it is proposed to develop not only an enormous amount of power for which there can be no market for years to come, but also to irrigate more than a million acres of land, largely in private ownership, for which there will be no demand within a still longer period.

Reclamation.—Almost the entire record of irrigation under Federal laws and Federal control in the United States has been a series of economic failures.

---

[16] Testimony before Appropriations Committee, 1936, *Proceedings*, Am. Soc. C. E., February 1938, p. 253.

[17] *Electrical World*, August 23, 1937, p. 260.

[18] *Loc. cit.*, p. 52.

The Carey Act of 1894 resulted, by 1925, in the irrigation of only 1 158 926 acres under private and corporate efforts. In general, the cost of bringing water to the land was so great that success was practically impossible. This was due (in part, at least) to promoters' profits. Such lands were partly colonized through misrepresentations, and, in many cases, the settlers lost everything in their attempt to cultivate the land.

In 1902, reclamation was started by the Government as a self-sustaining and self-liquidating venture. These projects were to be financed from a revolving fund. The time of payment was first planned at 10 yr, then 20 yr, and, finally, at 40 yr, but the funds refused to revolve.

The following description[19] of the situation that followed can but remind the reader of recent history. Such results are, with few exceptions, the indispensable condition of all Federal ventures into business:

> "Once irrigation work got under way, every state west of the 100th meridian besieged Congress to approve one or more pet projects. When government money was to be had for the asking, it put a new zest into politics. Here was something tangible to work for—pie to bring the faithful back home. * * * In consequence every patch of brown sagebrush became a prospective Garden of Allah in the mind of some one. All it needed was a Moses with his staff to make the water gush forth, and lo, the desert would burst into bloom.
>
> "Those were grand days for the promoters, the real estaters, the speculators, the chambers of commerce, the business men and the politicians. Of the latter every one who carried a staff aspired to be a Moses, and he was the most honored and the most loved who was able to bring forth the biggest fountain.
>
> "Every project had a political father and mother and a host of godfathers, sons, uncles, and other close relatives. * * *"

Flood Control.—The space available will not permit further consideration of Federal public works now under construction. The writer desires, however, to consider briefly the matter of Federal flood-control works that apparently is soon to become important. An appropriation of $34 177 000 chiefly for flood control on the Ohio River has already been passed and approved. This is only a start on the vast expenditure that may be involved in this important problem.

The public has many erroneous ideas concerning the cause of floods. When the writer was one of the commission called to China, in 1914, to determine what could be done concerning the control of the Huai River which frequently inundated its lower valley, it was found that the people of China believed that these floods were produced by the Hydra, a mythical dragon, which they believed dug into the hills and let out the flood waters. Even the average citizen of America smiles at such a crude idea but, nevertheless, believes in the no lesser superstition that floods in America are caused by "deforestation." It is apparently not generally known that floods, quite equal to any that have recently happened, occurred long before the forests of the United States were cut for timber. Neither does it seem to be understood that devastating floods occur only in valleys and lowlands which have been built up by the rivers in the past for the purpose of passing their flood waters. When mankind builds cities, factories, or farms on such lands, troubles from the occasional high floods must necessarily be expected. Flood control is, in fact, an attempt to save the people from the results of their own folly and ignorance, not in the cutting of timber, but in attempting to usurp the lands which the rivers occasionally need to discharge their maximum floods. In most cases, these lands, convenient to the river for the purposes of navigation, water supply, and pleasure, are the most accessible for railroads, highways, and buildings during normal river flow, and the most attractive sites for cities. The farm lands of the valleys and flood-plains, often greatly enriched by silt deposits, were naturally sought for farms. The great floods usually occur only at long intervals of time. The damages due to occasional floods were not great when the country was young and the people few in number. With the great growth of the centers of population and manufacturing often located in the exposed positions, flood losses have become enormous.

---

[19] Editorial in the *Country Gentleman*, January, 1927, p. 26.

Some communities that have experienced heavy losses in property and life, such as the Miami River Valley, have had sufficient energy and foresight to accomplish flood control at their own expense. Under present conditions of Federal spending, it is only to be expected that such communities are now calling on the Federal Government to save them from their own shortsightedness. The Federal Government has already committed itself to power development and flood control under the guise of navigation. Almost everywhere that floods are experienced, navigation either at the point where the damage occurs, or on the main river below, may be used as an excuse for Federal expenditures.

The writer believes that, in the future, with the precedent of the TVA and other recent Federal projects where flood control has been named as one of the objectives, the Federal expenditures for flood control will be one of the great items of Government expense. It is to be hoped that both public and political opinions may be so informed that their great and important works will be handled in an intelligent and economical manner.

In the last few years so much has been heard of "little waters," "up stream engineering," and "holding each drop of water when it falls," that at times it has looked as if flood control would be attempted by means of a few small reservoirs at the head-waters of streams, by a few small dams to prevent erosion, and by the planting of forests.

In his message to Congress, on floods, President Roosevelt has stated, however, that floods cannot be prevented by forests alone or by dams alone, but that such control demands the consideration of many factors. He has deferred action on the plans of the Army Engineers for certain flood-control projects until other interested Departments of the Government could be consulted. It is quite certain that the theoretical values of forest, improved farming methods, and erosion control will not be overlooked when these projects are finally considered.

The writer fully appreciates the importance of forestry, erosion control, and improved farming methods. All are important and should receive due consideration in their time and place. There is no question but that the creation of forests on the hills and mountains, the grassing of sloping fields, and the construction of check dams for preventing erosion, have an effect on run-off during moderate rains and will distinctly reduce ordinary run-off and even light floods. With frozen or saturated soils, however, and the downpour of maximum flood-producing rainfalls, such preventives of flood run-off are only as effective as footprints in a field, which may hold back water to a small extent, but are so utterly insignificant as to be unworthy of any consideration under these extreme conditions.

There are no men more interested in every means of reducing maximum floods than engineers who have studied the subject of flood control. The effect of forests on stream flow has been carefully investigated and thoroughly studied many times, but the writer has yet to be convinced from such studies that deforestation or reforestation has ever had the slightest practical effect on the maximum flood of any stream.

Forests for pleasure and profit, and for the prevention of erosion, have real value; and reforestation for its real intrinsic value has the earnest support of the writer.

The study of cause and effect is a somewhat difficult and intricate matter. The writer was in China at the time of a lunar eclipse. The natives thought that a dragon was attacking the moon. Fire crackers were exploded, gongs were beaten, and pandemonium broke loose. The results were apparently fully satisfactory. In a short time the trouble was over. The moon came forth serenely, even the part that had apparently been bitten out by the dragon was replaced. The moon was saved to the satisfaction of the Chinese people as it has been many times in the 4 000 yr of Chinese history and as it probably will be for hundreds of years to come. Such ideas are not confined to the Chinese. The writer found in the *Proceedings* of the Society not long ago the statement that the author knew that forests produced rainfall because he had frequently stood on the sunlit lowlands of Central America and had seen heavy rainfalls over the forests of the foot-hills and mountain slopes. Did the forests produce this rainfall or do trees normally grow where rain naturally falls? The people of the United States may, perhaps, receive a somewhat expensive answer to this question when they have the final results of the shelter belt, which, the writer understands, is still being planted on the Great Plains in spite of the refusal of Congress to appropriate money for that purpose.

Responsibility of the Engineering Profession.—The welfare of the future depends much on the Engineering Profession. The engineer, through his training and through his experience in connection with past enterprises, is best fitted to make a truthful analysis of the results which must be anticipated from most of these great projects. If he will assume the responsibility of informing the public concerning those matters, he can assist materially in creating and arousing an intelligent public opinion that will demand sane and intelligent consideration of future governmental activities.

The members of various Engineering Societies in Chicago, Ill., recently voted to subject Government public works projects to critical examination by competent members and to publish the findings. Similar action should be taken by every Engineering Society in America. Much good can be accomplished by such action. Will the Engineers and Engineering Societies of America rise to this important duty?

The engineering features of the TVA, of navigation, and other works done under the Army Engineers, of the Reclamation projects, and of such of the present projects, as the writer has seen, are, in general, well designed and well constructed and he has nothing to criticize in this regard. Fortunately to this extent politics has been eliminated; but sound engineering cannot make an uneconomical project an economic success.

Government projects, both in the present and in the past, have been based most largely on political expediency, especially when the Government has ventured into business enterprises. This has been true regardless of the party in power, whether Federalist, Whig, Democrat, Republican, or Progressive. The principle of spreading the spoils of Federal activities over the entire country in order to satisfy the electorate, regardless of any real justification of the individual projects involved, has become too well established and, in the opinion of the writer, is the only real explanation of many Federal activities of both the present and the past.

The Grand Coulee Project, as an immediate objective, was so utterly condemned by official reports of the Army Engineers, the Reclamation Service, and the Department of Agriculture before it was undertaken under executive order, that it seems hopeless to anticipate that Government undertakings can ever be based on sound economic principles, unless an intelligent public opinion can be both created and aroused to active influence in municipal, State, and Federal activities. The conditions prevailing at present are certainly a sad reflection on the present so-called civilization. Unless the thinking men of this country, the men who are willing to stand for a square deal, for sanity, for truthfulness, honesty, and intelligence, aside from party and aside from personal interests, soon begin to take an active part in public affairs, the writer sees little future hope for the success of democracy or of the American nation.

HAZARDS OF UNECONOMICAL CONSTRUCTION

BY HENRY EARLE RIGGS,[20] PAST-PRESIDENT, AM. SOC. C. E.

SYNOPSIS

The magnitude of the unemployment problem which faced the present Administration when it came into power, the country-wide extent of the relief program, the fact that billions of dollars have been paid out since 1933 either in the form of direct relief or for many hundreds of projects of work relief, and the multitude of different agencies for the distribution of relief funds—all of these influences have tended to divert the attention of the general public from the vast program of major public works which has been entered upon as part of the relief program by various Federal agencies.

Many of these great undertakings are wholly unknown to the public. Where they are located; what they are for; the great magnitude of some of them; the cost of them running into tens or hundreds of millions of dollars; the annual costs of interest, maintenance, and operation that will be incurred after they are completed; the assurance that they have of success or failure—all of these phases of the problem are a closed book to the great majority of taxpayers. The non-technical visitor to the construction work is awed by the immensity of it and is furnished with printed information, some of it in the nature of propaganda, which emphasizes the great size but is silent on all matters of economics.

What kind of projects should be adopted for the purpose of furnishing work relief? Is the nation justified, in a time of great stress, and of rapidly rising national debt, in engaging in business ventures that are new to Government in the United States? Is it economically sound to spend vast sums of money in building works for the far distant future, which are distinctly not needed now? Is it wise to build without long and careful planning when the building involves tens of millions of dollars? Is a project economically sound when it may be seriously questioned whether there is a public need for it, a demand for its services, or a doubt as to whether it can be self-liquidating?

These and other similar questions which are suggested by the present program of public works should be proper matters of discussion by the Engineering Profession. This paper is an attempt to present the available evidence not only as to a few of the projects approved in the four years, 1933 to 1937, but also of some projects of earlier administrations which undoubtedly can be classified as failures of publicly owned State and Federal business undertakings.

---

[20] Hon. Prof., Civ. Eng., Univ. of Michigan, Ann Arbor, Mich.

It is written for the purpose of directing attention to the need for long-time planning, by Congress, of Federal public works and of the necessity for establishing definite requirements as to accounting, publicity of statistics, and the elimination of subsidy in connection with the operation of any publicly owned business or public-service enterprise.

No criticism is made or is intended to be implied of the design or construction methods of the projects discussed. The work of the engineers on the design and the handling of the field work of construction on all the major projects which the writer has visited, is excellent. Bonneville Dam and the dams on the Tennessee Valley Project are fine examples of modern engineering skill. Grand Coulee Dam and Fort Peck Dam will be the greatest structures of their kind in the world. They will continue as great monuments in the desert to the ability of American engineers to overcome well-nigh unsurmountable difficulties.

The construction plant that is used on these major projects and the construction methods and administration come in for equal praise. The most modern types of labor-saving equipment are in use. The impression one gains on a visit to the work, whether it is done by contract or by force account under the Corps of Engineers of the U. S. Army or other Government agency, is one of utmost efficiency of men and machines. Whatever there is of future credit on account of these undertakings will belong to the designers and the builders.

The question is whether such projects are economically justifiable as relief undertakings. In many cases, projects have not been selected by the Congress and, in some cases, they have been adopted in the face of adverse recommendations by competent engineers. The fact that the construction of many of the projects constitutes an entry of the Government into direct competition with private enterprise in the electric power or transportation industries has no bearing on any of the criticisms made herein. The writer is a thorough believer in the regulation of public service corporations and in the public ownership of utilities whenever the public authority can give better service, or lower rates, or can safeguard health or other public interests, more effectively than private corporations. He is by no means convinced, however, that Government ownership and operation of great and complex utilities is likely to be as successful or as efficient as fully regulated private ownership. A study of the results of Federal and State ownership does not tend to increase confidence in the success of many of the businesses thus involved.

This paper is an attempt to present exact facts regarding certain selected projects, both old and new; to present analyses and comparisons which throw light on the economic phases of the projects; and to indicate the financial hazards attendant on the hasty adoption of projects for great public works for which no complete surveys have been made, for which final plans and estimates are not available, and for which not only have no contracts for the sale of the product been made but, often, no present market for the product is in sight.

PASSAMAQUODDY TIDAL POWER PROJECT

The first example of present-day projects selected is the Passamaquoddy Tidal Power scheme, situated within two miles of the Canadian International Boundary on the Maine coast. This is an electric power project. As originally adopted by the Public Works Administration (PWA), it was a modification of a promotor's scheme which had been under discussion for about twenty years. The plan was to develop power from the high tides at the mouth of the Bay of Fundy by creating a reservoir out of Cobscook Bay, in Maine, which should always be held near high-tide level. Power would be generated by releasing water from this reservoir through turbines after the tide had fallen 4.5 ft, and continuing through low tide and until the rising water had returned to a level of 4.5 ft below that in the reservoir. This would permit power development for about 7 hr out of every 12. Because of the constant change of head during the 7-hr period and the fact that in each month the range of tides varies from about 10.5 ft to 24 ft, there can be no possible uniformity of power output, and, consequently, a small amount of firm power when the total installed capacity is considered.

To supply power during the 5 hr of each 12 when tidal power is not available it was proposed to build an artificial reservoir about 120 ft above sea level, to use the secondary power developed during the 7 hr of tidal operation to pump sea water into this high-level reservoir, and to permit it to run back into the ocean and operate turbines during the 5-hr period and thus furnish the power required for the stand-by plant.

The original plan for an international project was rejected in 1925 and 1926 by responsible private interests. The modified plan was submitted to the PWA in 1933 and twice rejected, and again turned down as unjustifiable after hearings by the Federal Power Commission. The original request to the PWA was for $47 000 000.

On May 16, 1935, Harold Ickes, Secretary of the Interior, announced that his Allotment Board had approved an allotment of $10 000 000 initially on an estimated total cost of $36 284 000.

The task of building the project was assigned to the Corps of Engineers, U. S. Army. Preliminary construction work was begun at once, and at the same time extensive surveys, explorations, and research studies were carried on and an estimate of cost was made. That estimate, which has never been made public, is known to approximate $62 000 000. Shortly after it was submitted, a commission of three nationally known and thoroughly competent hydraulic engineers (Charles H. Paul and Joseph Jacobs, Members, Am. Soc. C. E., with

Professor William F. Durand, of Stanford University) was appointed and directed to review and reconcile all estimates of cost. That report likewise has been filed and not made public. It approved in general the plans proposed by the Corps of Engineers, and the estimate of the cost of construction was somewhat higher than was estimated by the Army Engineers.

It does not seem out of place to emphasize here the fact that these are but two of a large number of engineering reports which should be available to members of the Congress, the public, and the Engineering Profession but which repose in the files at Washington, D. C.

The estimate of $62 000 000 was based on the original plan which included the high-level pumped storage reservoir and was for the same work covered by the estimate of $36 284 000 given out by the Secretary of the Interior at the time the project was approved. The Army Engineers proposed a revised plan which eliminated this high-level reservoir and substituted therefor a Diesel or steam plant as an auxiliary source of power to be used when the tidal power plant was non-operative. The estimated cost of this revised plan was approximately $37 000 000.

A paper by Captain Hugh J. Casey, Corps of Engineers, U. S. Army, M. Am. Soc. C. E., presented before the Boston (Mass.) Section of the American Institute of Electrical Engineers,[21] stated that the tidal plant will be capable of producing "a continuous output of 30 000 kw on a 100% load factor" and that "the combined plants will be capable of an annual net output of 260 000 000 kw-hr of prime energy."

It is obvious that either $62 000 000 or $37 000 000 for a plant with a firm power capacity of only 30 000 kw is many times the cost of a modern steam plant. It is equally obvious that if a steam or Diesel plant is built for stand-by use during 5 hr out of every 12 there is no reason why it should not operate all the time. If this stand-by plant is built it reduces the tidal power part of the project to an absurdity. It is evident that none of the engineering boards that studied this project for private interests or for the PWA between 1924 and 1933 could find any market that would warrant such an expenditure. The data published by the Federal Power Commission indicate beyond any question that there is no present market for this power in Maine.

In July, 1935, the Hon. Louis J. Brann, Governor of Maine, appointed a commission composed of Kenneth C. M. Sills, President of Bowdoin College; and Messrs. W. K. Campbell, W. F. Cram, H. B. Crawford, and E. S. French. The report[22] of the Commission which finally secured favorable action by the Administration made no attempt to justify the project as economically sound. This report stated:

> "We would argue for federal support for this project largely on the grounds of social desirability, that is, of benefit in the long run and in many ways without definite assurance that the project would be within a definite number of years self-liquidating. * * * In the present economic situation private capital would not be available and the government has already denied a loan to a private corporation on the ground that a sufficiently sure market for the power generated has not been shown."

---

[21] Not published.

[22] *Portland (Me.) News.*

Approximately $12 000 000 was allocated to this project. Work on housing, surveys and explorations, research studies, and some minor construction work—all costing slightly more than $6 000 000—was done before Congress refused to make any further appropriations.

IMPROVEMENTS FOR NAVIGATION

The second illustration that comes to mind is a navigation project. Navigation on the Missouri River by stern-wheel steamers commenced prior to the Civil War. It was of major importance to the West in the days before the railroad and, although the tonnage moved was not very large, it continued during the period 1860 to 1885, when the railroad network had fully covered the district between the Mississippi River and the Rocky Mountains.

The first appropriations for improvement work on the Missouri River were made under the River and Harbor Act of August 14, 1876,[23] and the original plan for comprehensive improvement of the river was adopted August 2, 1882.[24] The earlier Republican Administration initiated these expenditures on the Missouri River; and the present projects were adopted or modified in 1912, 1917, and 1927. Only the Fort Peck Dam Project was adopted under the present Administration. Therefore, prior Administrations must share any criticism as to the propriety of the great expenditures on this river. Over the years from 1876 to June 30, 1933, the total expenditures for new work and maintenance was a little less than $95 000 000, and during those years it was termed by the critics, "pork barrel legislation."

On October 3, 1933, "it was recommended to Congress that the project for navigation on the main stem of the Missouri River as heretofore authorized, namely from the mouth to Sioux City, be vigorously pressed to completion, and that, in addition the reservoir at the site of Fort Peck be built to the maximum practical capacity, and be operated primarily for navigation."[25]

During the first three years of the present Administration $47 000 000 was spent on this river improvement, and more than $60 000 000 of an estimated $109 000 000 was spent on the construction of Fort Peck Dam,[26] so that the net total of Federal money spent for navigation on the Missouri River to June 30, 1936, was $202 495 633, and the total appropriations amounted to $248 232 000, leaving $45 736 000 of available funds for work in the fiscal year 1937. To complete Fort Peck Dam another $18 500 000 will have to be appropriated, bringing the total for navigation on the Missouri River to $267 000 000, or more.

At least 90% of the reported traffic on the Missouri River was material for Government construction, and has been for the past eight or ten years. In 1929, when total traffic was reported as 1 372 000 tons, all except 6 155 tons was noted as "used in river improvement and moved by owners." Since that year specific items used in Government construction are not indicated but the general footnote appears in each yearly report, as follows, "a large percentage of the traffic reported was for river improvement work."

[23] Rept. of Chf. of Engrs., U. S. Army, 1933, Pt. I, p. 712.

[24] *Loc. cit.*, p. 707.

[25] *Loc. cit.*, p. 708.

[26] Rept. of Chf. of Engrs., U. S. Army, 1936.

There can be no possible criticism of reasonable Federal expenditures for keeping navigable and navigated waterways and harbors in condition for use. Comparatively few such waterways can be self-liquidating and the value of any of them to the public is incapable of exact determination, such value being principally in the form of modified rail rates over large areas due to the competition of water transportation. One yardstick of the economic justification of these expenditures on the Missouri River can be had by comparison with like expenditures on the Great Lakes, and by a comparison of the tonnage and value of freight moved on the two waterways.

The total cost of all capital and maintenance expenditures on the Great Lakes between 1824 and 1936, including all work on the harbors of the Great Lakes and the navigable rivers entering them, all connecting rivers such as the Detroit, St. Clair, and the St. Marys, with the locks at the "Soo," in short, all Government expense of every kind on this great system of internal waterways, was $248 277 000, or almost exactly the same as the appropriations on the Missouri River to the same date ($248 232 000).

In 1935 gross total traffic at all Great Lakes ports totaled 186 879 000 tons, or more than 101 times as much as the 1 841 000 tons reported on the Missouri River, nearly all of which was construction material, and therefore, temporary traffic. The total value of Great Lakes freight was $2 913 070 000 which is 236 times as much as the $11 941 000 total freight value on the Missouri River. If the expenditure of $95 000 000 for navigation on the Missouri in a period of 57 yr was "pork barrel" is not the appropriation of $153 000 000 in three years "pork barrel supreme"?

FORT PECK DAM

Fort Peck Dam has been considered as part of the Missouri River navigation project. Further brief reference to it appears to be necessary. This great structure is about 1 600 miles northwest of Kansas City, Mo., in North Central Montana. It will be the world's largest earth dam, requiring more than 100 000 000 cu yd of earth and gravel in its construction, with spillway, tunnels, and auxiliary structures of equally imposing magnitude. It began with an estimated cost of $86 000 000.[27] The revised estimate of 1936 places the cost at $108 600 000.[26] It is expected that all major structures will be finished by June 30, 1938, and that the dam itself will be finished and placed in operation in the autumn of 1939. It is a magnificent piece of engineering design and construction, and no possible criticism can attach to the builders of it.

Although the plans provide for a possible future power plant there is small likelihood of one being built except for irrigation pumping as the territory is sparsely settled and there are not more than three or four towns with more than 5 000 population within a 150-mile radius. Ample power is now developed in the western part of the State to meet every requirement for years to come. No present irrigation development is proposed, although, like power, this is a possible future by-product of the dam.

---

[27] Rept. of Chf. of Engrs., U. S. Army, 1934.

The Division Engineer of the Corps of Engineers, U. S. Army, is quoted[28] as placing $3 000 000 as the justifiable expenditure at Fort Peck for flood protection in the river below St. Joseph, Mo., and he states, further, that "it would have little if any effect upon Mississippi floods."

This clearly is a navigation project. It will insure the maintenance of a minimum flow of 30 000 cu ft per sec at Yankton, S. Dak., and at points down stream. Power, irrigation, and flood control are practically "out of the picture."

This dam will be completed within a year or two. Water is now (1938) flowing through the tunnels, all the auxiliary structures are nearing final completion, and there will be left after this year only the completion of the earth dam.

POWER IN THE NORTHWEST

In the summer of 1933, in the first wild rush to find projects for putting the unemployed to work at once, $63 000 000 was allocated by the PWA for the construction of a low dam, which later could be increased in height, across the Columbia River at the head of the Grand Coulee, in Northern Washington, and the building of a power "yardstick" for the Northwestern States. This project had been estimated by the Army Engineers to cost about $108 000 000.[29]

Politics "got to work" as soon as this project was approved. The State of Oregon had a power and navigation project for which it demanded approval, and within a few weeks $31 000 000 was allocated by the PWA to the Bonneville Dam and Power Plant, which was close to the power market, which alone was capable of furnishing as much power as will be needed in the area, and which extends deep-water navigation about fifty miles to The Dalles, Ore.

Construction at Grand Coulee was put in charge of the Bureau of Reclamation, a contract for the dam and power plant was entered into on July 16, 1934, and work on the dam was actively begun.

The fact that the Government had commenced work on two power projects, either of which was capable of meeting all reasonable present or anticipated needs for additional power in Washington, Oregon, and Idaho, the three States having the cheapest power in the country and the greatest per capita consumption of power, indicated the necessity for a reconsideration of the original plans for Grand Coulee Dam. Therefore, extended studies were made by Engineers of the U. S. Bureau of Reclamation, and on June 5, 1935, an official order was issued changing the contract from one for the low dam and power house to a contract for the foundations of an ultimate high dam[30] which would back water to the Canadian Boundary and constitute the first step in a gigantic project to irrigate more than a million acres of land known as the Columbia Basin.

The plan adopted by the Bureau was one which promotors had been urging for a number of years, in which irrigation was the final objective, but irrigation which could only be justified if it was subsidized by the sale of vast quantities of power. The order made most revolutionary changes in the contract, substituting foundation work on a much larger dam, for the originally planned complete low dam and power plant, all in the bed of a swift river with a mean flow of more than 100 000 cu ft per sec, and a maximum recorded flow of 460 000 cu ft per sec,[31] involving increases in quantities of more than 3 000 000 cu yd of common excavation and more than 850 000 cu yd of mass concrete. The contractor was to do this work for the same price as that named in the contract for the original project "subject to adjustment."[30]

---

[28] *Engineering News-Record*, November 29, 1934.

[29] House Doc. No. 103, 73d Cong., 1st Session, p. 735.

[30] Paper by Kenneth B. Keener, Senior Engr., U. S. Bureau of Reclamation, *Engineering News-Record*, August 1, 1935.

The Columbia Basin Reclamation Project, substantially as now contemplated by the Bureau of Reclamation, was estimated by the Corps of Engineers, U. S. Army, in its study of power, irrigation, and flood-control possibilities on the Columbia River, as follows:[32]

Total for power and navigation............	$215 483 453
Total for irrigation......................	221 721 880
Total power, navigation and irrigation.......	437 205 333

This was a preliminary estimate and, in view of the unprecedented difficulties of construction, may conceivably be substantially exceeded. A statistical abstract of the "United States Under Government Irrigation Projects" shows the charge to irrigation of $11 419 070 of the cost of Grand Coulee Dam to June 30, 1935. Inasmuch as the entire cost of the river dam is charged to "Power" in this estimate the final distribution of cost will be very different from these data.

The present work under contract includes only the foundations of the Columbia River Dam, of which Kenneth B. Keener, Senior Engineer of the Bureau of Reclamation, states:[30]

> "* * * completion of the Grand Coulee Dam is a problem for the future and one that need not be given serious consideration until the work now under contract is nearing completion. Conditions and requirements at that time will no doubt govern the next step to be taken in the development of the Columbia Basin project."

Within a year or two at the most Congress will be asked for more money to continue this project. That body may very properly ask just what it is proposed to do, why it is needed, and whether the project will be self-liquidating. The dam is advertised in literature given out to visitors to be "the world's largest masonry structure, larger than the great pyramid, four times as long as Boulder Dam." It will be 500 ft high, 4 300 ft long; it will contain 11 250 000 cu yd of concrete, and will involve 16 000 000 cu yd of excavation. According to a tabulation of the Bureau of Reclamation the power plant will have a rated capacity of 2 500 000 hp, and will be able to develop 7 000 000 000 kw-hr of firm power and more than 4 000 000 000 kw-hr of secondary power per yr. This rated horse-power capacity is almost 16% of the rated capacity of all the water-wheels in the United States,[33] and more than the 2 358 000 hp of the California turbines. It is made perfectly clear in the report of the U. S. Corps of Engineers that "the feasibility of the pumping plan [this project] is dependent on the possibility of selling practically the entire output of primary power from this plant at a remunerative rate."[34] The late Elwood Mead, M. Am. Soc. C. E., has stated:[35] "This development to be solvent must be based on revenues from power and these revenues must contribute to the cost of the irrigation works to avoid injurious burdens on irrigation farmers." Therefore, the first consideration as to this plant is the question of market for power.

---

[31] Rept. of Div. Engr., H. R. Doc. No. 103, 73d Cong., 1st Session, p. 58.

[32] H. R. Doc. No. 103, 73d Cong., 2d Session, p. 15.

[33] Given as 16 179 475 hp as of January 1, 1937, in the Dept. of the Interior Press Memorandum, dated February 16, 1936.

In considering the market it must be remembered that Bonneville, in Northern Oregon, is in the same territory. The Bureau of Reclamation states that 7 000 000 000 kw-hr of firm power will be generated at Grand Coulee. The statement has been made[36] that the two dams on the Columbia—Bonneville and Grand Coulee—will have a combined final installed capacity of 2 322 000 kw and can produce 10 220 000 000 kw-hr.

The combined capacity of the two plants is greater than that of all classes of generating equipment of any State in the Union in 1935, except only New York and California. It is 840 000 kw in excess of the total equipment in Oregon, Washington, and Idaho, in 1935.[37]

The total power generated in that year in the eight States of Oregon, Washington, Idaho, Montana, Wyoming, Colorado, Utah, and Nevada was 6 772 000 000 kw-hr or less than the firm power capacity of Grand Coulee alone. The total power generated in Oregon, Washington, and Idaho, which is where these plants must find their market, was only 4 570 281 000 kw-hr.[37]

Need anything more be said? Any study of the power market in the Northwest indicates that there would be difficulty in finding a market at present for 1 000 000 000 kw-hr, and the market for any such amount as would justify Grand Coulee as a power project is more than a generation in the future.

THE COLUMBIA BASIN PROJECT

This Grand Coulee Project cannot be dismissed without emphasizing the fact that, in 1927, six years before the emergency approval of Fort Peck, Grand Coulee, and Bonneville, the Congress attacked the problem of the wise and proper development of the Columbia River in a highly proper manner. In that year an Act was passed providing for an exhaustive study of certain rivers, including the Missouri and Columbia, with the view to determining the possibilities for the development of navigation, flood control, power, and irrigation, on these great rivers.[38] One of the so-called "308 reports" dealing with the Columbia River is dated July 31, 1931, and was available to the Federal officials in 1933 when Grand Coulee was approved as a project.[39] This report discussed the building of either eight or ten dams which would develop more than 92% of the total head of the Columbia between the International Boundary and Tidewater. Of these dams, one at Warrendale, Ore. (or Bonneville as an alternate site), was the lowest, at Tide-water, and the one at Grand Coulee was the last one before reaching the International Boundary. The Corps of

[39] H. R. Doc. No. 103, 73d Cong., 1st Session.

Engineers of the Army went at length in this report into the consideration of building Grand Coulee in connection with the Columbia Basin irrigation. Apparently, the fact that this was a promoter's project was the reason for the exhaustive study of it.

A careful analysis of this report disclosed strong adverse recommendations to the project now under construction; for example, Maj. Gen. Lytle Brown, U. S. Army, M. Am. Soc. C. E., then Chief of Engineers, U. S. Army, stated:[35] "In fact the local reports demonstrate that the irrigation of land as pertains to the Columbia River area under consideration is not an economical proposition at this time and should await the future."

The Board of Engineers for Rivers and Harbors stated:[34]

> "One large area of upland known as the Columbia Basin could be irrigated by gravity from the Clark Fork and Spokane River or by pumping from the Columbia River by means of secondary power developed at the plant near Grand Coulee. The feasibility of the pumping plan is dependent on selling practically the entire output of primary power from this plant at a remunerative rate."

Subsequently, the Board discusses this subject at length, as follows:[40]

> "The economic feasibility of this plan is largely based on subsidizing irrigation by profits from the sale of power. * * * The Board * * * is of the opinion that the estimates of the reporting officers that the growth of power demand will be such that the entire prime output would be absorbed in a period of 15 years after 1940 * * * is unduly optimistic. * * * The Board * * * is unable to recommend the adoption of this project at this time."

This report, dated March 29, 1932, was available when the project was decided upon and is full of sound argument why Grand Coulee should not be built. A "Report on the Columbia Basin Project," dated February, 1925, two years prior to the action of Congress ordering the Corps of Engineers, U. S. Army, to make its study, was addressed to the U. S. Bureau of Reclamation by Louis C. Hill, Past-President, Am. Soc. C. E., Joseph Jacobs, Charles H. Locher, Richard R. Lyman, and A. J. Turner, Members, Am. Soc. C. E., and Mr. O. L. Waller. This Board found that economic conditions definitely favored the adoption of a gravity project by diverting water from Clark Fork at Albany Falls, which would cost $158 per acre to irrigate 1 224 000 acres, and did not deem it necessary to make an elaborate analysis of the Grand Coulee scheme.

Discussing Grand Coulee on March 19, 1912, Elwood Mead stated:[35] "It will require at least ten years after the works are authorized, to build the dam and power plant, and another ten or fifteen years to absorb the power thus made available. These things must precede the large expenditure to build the works required for irrigation."

It is impossible in such a paper as this to brief all the evidence fully. To the writer the essential points appear to be as follows:

(1) In 1925, a study of the irrigation project was made by the Hill Commission which recommended a gravity system at a cost of $158 per acre. This report has not been made public, but apparently the total cost of the gravity plan approximated $195 000 000.

---

[40] H. R. Doc. No. 103, 73d Cong., 1st Session, p. 12.

(2) In 1927, the Congress ordered the Corps of Engineers of the U. S. Army to make a study of the entire Columbia River and to report on the possibilities of navigation, irrigation, power, and flood control. This was done and an 1 845-page report was submitted which considered this specific project at length, and which did not approve it.

(3) It appears from various sources that the larger part of the land in question is in private ownership, much of it in the hands of bankers and speculators.

(4) The project as first approved by PWA was for an entirely different plan involving only power but with a low dam which, subsequently, could be raised in height. Later, this plan was abandoned and the change to the large power development to support the irrigation scheme was made by the Bureau of Reclamation.

(5) It does not appear that the project was presented to the Congress before its adoption or discussed by Congress in the light of the report to it by the Corps of Engineers, and with full understanding of the magnitude of the undertaking.

(6) The Corps of Engineers' estimate of cost of the present project was $437 000 000. The Statistical Abstract for 1936 shows the total cost to the Government of all the forty-five other reclamation projects of the Federal Government, excluding all charges to the Grand Coulee project, to have been less than $237 500 000. Based on charges to date to irrigation on this project, it is evident that this one irrigation project alone will cost more than all previous Federal reclamation projects, and the entire project will exceed the cost of the Panama Canal by many millions of dollars.

(7) A study of existing power development in Oregon, Washington, and Idaho, a large percentage of which is publicly owned by the Cities of Seattle and Tacoma, Wash., and of the production and sale of power in these States, seems to indicate that there is no possibility of the sale of all the power of both the present Bonneville installation and Grand Coulee; but all the power of Grand Coulee must be sold at a profit to subsidize irrigation in order to justify the scheme.

It is to be hoped that the Congress will not take hasty action in approving further appropriations for this project without the most complete expert study. The request for more money, which will inevitably be made by 1938, should be cause for an exhaustive study and a report which will be available to the public by a commission of nationally known, highly qualified, and wholly disinterested engineers. If there is no market for practically all the energy (and that appears to be the fact) the entire project will fall.

Freely granting the urgent need that existed in 1933 to find public works to relieve unemployment, the writer is of the opinion that such a project as this one, which will require years to complete, and which may involve half a billion dollars, does not fall into the class of emergency relief works. It should never have been adopted without the full discussion and consideration of Congress.

"COUNTING THE COST"

The nation will do well to count the cost of the great program of public works which has been commenced. The sums of money published as the estimated cost of construction are imposing enough in themselves, and would total somewhere between $1 000 000 000 and $2 000 000 000, if all the major projects were listed (such as the ones already named, and others like the Tennessee Valley Authority, the Florida Canal, Central Valley, California, and other Federal projects, and such Federal financed State undertakings as the Central Nebraska Power Project, the South Carolina Public Service Authority, and the Lower Colorado Authority in Texas).

In "counting the cost" it is not the intention herein to consider anything except actual cost which sooner or later must be paid in the form of taxes. Possible losses of private capital invested in power properties or transportation agencies whose business may be injured and whose credit may be wrecked by competing Government agencies, or the possible destruction of industries such as that of the salmon fisheries by the building of dams, may be substantial, but they are controversial matters which will not be discussed.

Too much emphasis cannot be placed on the fact that every dollar that is invested by the Government in river improvement in aid of navigation, in great dams to regulate the flow of streams in aid of navigation, in power plants for the manufacture of electric energy, in irrigation, or in any other public service, is a dollar added to the public debt. Whether the project is wise or foolish, every dollar that it costs adds to the national debt and contributes in proportionate amount to the annual burden of interest.

Exactly the same sound business principles should control the selection of public construction projects which are to render a service that the public must pay for as would prevail in the case of a successful private undertaking of the same kind. Many of the plants now being built appear to be foredoomed to failure because of the adoption of the project without adequate study of the site, or complete and accurate plans, or without a proper economic study to determine whether they could be self-liquidating.

The ultimate cost to the taxpayers is the final cost of the project with all of the auxiliary construction made necessary for its complete use, plus all interest and other fixed charges as long as any part of the cost is not amortised, plus all deficits in operation and maintenance less than total revenues.

This may be made more definite by a consideration of actual cases to show that:

(*a*) Imperfect explorations and preliminary and partly digested plans result in misleading and inaccurate estimates, in large contingent expense due to unforeseen difficulties, or to the need for changes in plan after the beginning of work.

(*b*) The adoption of plans for a single project which may take years to build (such as a great dam and power house), involves the building of auxiliary structures to permit its complete use, such, for example, as the transmission lines and sub-stations needed to permit the power plant to serve the market.

These structures must inevitably be built, but no estimates of their cost have been made public by Federal agencies.

(*c*) Where the economic studies of the market and of probable future growth of business were over-optimistic or just plain "bad," the resulting business losses extending over many years, plus fixed charges, constitute an intolerable burden.

These conditions have occurred in the past on numerous occasions when the Congress was misled or was at fault by reason of political pressure. A large part of the public works now in progress (1938) were hastily approved by temporary emergency boards and commissions, with a changing personnel, acting under a pressure not unlike that during the World War when hundreds of millions of dollars were wasted in building nitrate plants that never operated and ships that never sailed. The magnitude of these projects far exceeds anything ever undertaken in a like period of time in the United States.

These hazards of uneconomic public works, construction cost that cannot be repaid, great expense of auxiliary plant not now disclosed, fixed charges that cannot be carried by the project and that may never be reported in its operation, and possible operating losses, cannot be cured by the "writing off" of part or all of the capital account. This has been done in the past, and on the books the account of the particular project looks better. That, however, retires no bonds; nor does it reduce the taxpayers' annual burden of interest. It merely transfers the item to other general accounts. Every project which involves Government in business and which is built as a self-liquidating enterprise, should be compelled by the Congress to keep its accounting records so as to show every transaction, and to carry as its share of fixed charges every dollar that the nation is obligated for by reason of its construction. Failure to treat interest as a deduction from gross revenue is by no means rare in the accounting of publicly owned plants, especially those that are not successful.

SIGNIFICANCE OF CONTINGENT EXPENSE

A study of the annual reports of the Chief of Engineers of the U. S. Army discloses the fact that Bonneville Dam affords an excellent example of contingent expense due to the hasty adoption of sketch plans based on only a preliminary investigation of the site.

Under the National Industrial Recovery Act the sum of $20 250 000 was allotted to the project on September 30, 1933. Actual construction began in October, 1933. Confident that the preliminary plans were sound, construction work was in progress at the same time that surveys and explorations for the final plans were being made. The details of the preliminary estimate of the dam and power house with two units, totaling $31 000 000, were published in 1934.[41] The PWA allotted an additional $11 000 000 to this project in August, 1934, making a total allotment of $31 250 000.

Detailed study of the site as work progressed indicated that the spillway section of the dam (north of the island) should be moved down stream about

---

[41] *Engineering News-Record*, November 1, 1934.

3 000 ft. This was done and contracts for the dam and power house were let. In the report of the Chief of Engineers for 1934 the estimated cost was placed at $40 000 000.

Salmon fishing is a most important industry in the area, and public clamor was such that most elaborate fishways and fish locks were installed. The total cost of these provisions for the passage of fish in the river approximates $4 000 000. The Chief of Engineers' report for 1935 gives "the estimated cost of the dam, lock, two power units, and fishways as $42 415 700." The navigation lock was changed from 350 ft to 500 ft in length, and from a depth of 15 ft over the sill to 27 ft. This change cost approximately $1 200 000.

The Chief of Engineers' report for 1935 stated[42] that the project was "adopted by the River and Harbor Act of Aug. 30, 1935." In other words, Congressional approval was not secured until two years after the work was begun. The Annual Report for 1936 states that the estimated cost revised in that year is $51 000 000.

These facts are not presented in any spirit of criticism of the Corps of Engineers, which is doing a magnificent piece of construction; nor is it implied that Bonneville is not economically justified. The writer believes that if there is any warrant for this class of Federal expenditures, Bonneville can be classed as a self-liquidating project. The subject is discussed to illustrate the fact that when such a difficult project as one of these Columbia River dams is selected without the benefit of complete explorations and preliminary plans, and construction is begun immediately, the inevitable result is a great contingent expense the cost of which must be provided for by a further appropriation of funds raised by taxation. In this case the Administrators of the National Recovery Act and the PWA allocated $31 000 000. Two years later, the orphan was "adopted" and Rivers and Harbors appropriations have had to take care of the additional $20 000 000 which was not anticipated.

Estimates made by the U. S. Corps of Engineers include liberal allowances for engineering, interest not only during the period of actual construction but up to the time when the plant is on an earning basis, and all legitimate over-head costs. Contingent costs due to changes of plan, difficult foundations not disclosed by the preliminary survey, weather, flood, or bad soil conditions may increase the final cost of the work from 10% to 50%, or more, beyond the estimate.

Here are two Army built projects so nearly completed that the difference between the 1934 estimate and the revised estimate of 1936 may be accepted as the cost of contingencies:

Dam	1934 Estimate	Revised Estimate of Final Cost
Fort Peck	$86 000 000[43]	$108 600 000[26]
Bonneville	31 250 000[44]	51 000 000[45]
Total	$117 250 000	$159 600 000

---

[42] Rept. of Chf. of Engrs., U. S. Army, 1935, p. 1315.

[43] *Loc. cit.*, 1934, pp. 641, 742.

[44] *Loc. cit.*, pp. 1335, 1337.

[45] *Loc. cit.*, 1936, p. 1517.

The excess cost over the originally stated estimate is $42 350 000, or an over-run of 36 per cent. If the final cost of Grand Coulee should exceed the estimate of the Corps of Engineers, made under exactly the same conditions as those for Bonneville and Fort Peck, by the same percentage, it means the addition of $157 394 000 of unforeseen cost, or almost as much as the total final cost of Fort Peck and Bonneville. Any one who has visited the site of Grand Coulee in the remote desert, with a wide, deep, and swift river to contend with, whose maximum flood is 300 000 cu ft per sec in excess of the mean flow, can realize that such a contingent expense is entirely possible. These data are based on estimates of the Corps of Engineers, a body capable of making fully as accurate estimates as any other governmental agency or, indeed, as any engineers. The reports of the Chief of Engineers give facts in such full detail as to inspire absolute confidence.

The fact seems to be that the data issued at Washington as the estimates of cost of these major public works projects do not represent the final cost, and that tens of millions of dollars more will have to be provided to complete the work now under way.

Supplementary Costs

Auxiliary construction made necessary by the completion of Federal emergency projects, of which no mention was made at the time of approval of the work, constitutes another great source of future expense.

On December 10, 1935, a Committee on Power of the Oregon State Planning Commission, of which J. C. Stevens, M. Am. Soc. C. E., was Chairman, submitted a report on the "Cost of Bonneville Power." This Committee estimated the capital cost of a transmission system, including receiving sub-stations, for the adequate distribution of power from the finally completed Bonneville plant with ten generating units to Oregon communities, at $43 270 000.

The report of the Division Engineer of the War Department, North Pacific Division, on the study of the Columbia River,[46] refers to this subject of power transmission. No attempt is made to submit any final plan, or total estimate of cost of transmission lines and transformer stations needed to carry the Grand Coulee power to market.

Appendix II of this report includes a study of this problem by Dean Edgar A. Loew, of Washington University.[47] Data in this estimate give the cost of one double-circuit, 220 000-volt line, with its terminal equipment estimated for several circuit lengths, using Government construction costs with interest at 4%, as shown in Table 4.

What has been stated regarding the capacity of these two plants makes it very obvious that the Federal Government has an extremely serious marketing problem, and a very costly auxiliary construction project ahead of it to get the more than 7 000 000 000 kw-hr from Grand Coulee Dam to any possible market.

---

[46] H. R. Doc. No. 103, 73d Cong., 1st Session, pp. 48–49.

[47] *Loc. cit.*, pp. 456–479.

This same problem of transmission of power will be found at every one of the Federal power projects and will call for tens of millions of dollars in nearly every case. Not only are there no definite figures as to the cost of the dams and power plants, but it is impossible to determine for some years the number of millions, or hundreds of millions, of dollars that must be incurred in transmission costs to which the projects are committed.

TABLE 4.—COST OF ONE DOUBLE-CIRCUIT, 220 000-VOLT TRANSMISSION LINE

Length of line, in miles	Peak capacity, receiver end	Investment	Annual expense of operation and maintenance	Annual fixed charges*
100	325 000	$8 078 200	$30 000	$551 700
150	271 000	8 495 700	45 000	580 300
200	216 000	9 144 400	60 000	624 600
250	162 000	9 933 600	75 000	678 500

* Fixed charges include interest at 4%; depreciation reserve at 1.78%; and amortization at 1.05%; total, 6.83 per cent.

OPERATING LOSSES UNDER GOVERNMENT OWNERSHIP

The third hazard which has been referred to is that of operating losses on unsuccessful projects. This can best be illustrated with certainty by turning to the history of operating projects.

The experience of the Federal Government in business does not lead one to be optimistic about many of the projects now under construction. Several of the States have engaged in enterprises that have proved disastrous. One or two notable exceptions tend to emphasize the fact that the more far flung the enterprise and the more centralized the administration of it the greater is the certainty of failure.

Municipal ownership, being nearer home, where the taxpayers are neighbors of the officials, has done better. There are scores of examples of well managed and profitable publicly owned water-works. There are several notable examples of highly successful and well operated municipal electric plants in large cities, giving good service at low rates and full and fine publicity to statistics based on accounting that is done in accordance with the most approved classifications. There are many such plants in smaller cities that were built as publicly owned properties in the early days of the industry, which have been, for many years, in charge of non-political commissions and skilled managers, and which compare favorably in service and rates with privately owned utilities of comparable size. On the other hand, there are apparently more than a thousand small-town electric plants that are miserable failures—many more failures than there are good plants.[48]

Early State expenditures for canals were great and there were many projects none of which paid expenses for more than a brief period and none of which ever paid much, if any, interest, to say nothing of any return of capital. The principal surviving canal, the New York Barge Canal, successor to the Erie Canal, had cost the State of New York nearly $300 000 000 from 1903 to 1933. At the time that the Barge Canal System was authorized in 1903, State funds of New York had already been drawn upon to the amount of $73 000 000 in excess of canal revenues for the support of the old Erie Canal. In 1933, a total of 4 000 000 tons of freight was moved, and the annual maintenance and operating expense was $2 788 000.

---

[48] "Do Municipal Electric Plants Really Pay?" by H. E. Riggs, *Public Utilities Fortnightly*, September 24, 1936, pp. 363–392.

Prior to the Civil War and extending into the 1880's several of the States expended large sums of money on railroad construction, nearly all of which was lost. Only the State of Georgia with its Western and Atlantic Railroad can report a successful investment. This road, still owned by the State, has been leased for more than fifty years at a rental which pays a fair return on its cost.

The Alaska Railroad cost the Government $70 110 000 to June 30, 1930.[49] Not in any one year since it began operating in 1916 has it paid its operating expenses. Added capital investment and interest on the capital have all been met by the taxpayers, in addition to making up the deficits. This property is 540 miles long, serving a population in 1930 of less than 8 400 in a tributary area of 50 000 sq miles, with very little export freight. In the fiscal year 1930 it moved 915 freight car loads.[50] The Government has spent more than $6 000 000 building a highway from Valdez to Fairbanks. In the report of the Senate Committee, the late Hon. Benjamin F. Howell, U. S. Senator from New Jersey, stated:[51]

> "These facts afford a notion of the competitive potentialities of the government built and maintained highway in juxtaposition with the also government built and maintained Alaska Railroad, and it well might be urged that these facts also denote, at least, an apparent lack of coordination in the practical promotion of government activities."

In this same report, the following statement appears: "A factor, other than inadequate passenger and freight rates, that contributes to the annual deficits is looseness and inefficiency in the conduct of railroad business and affairs and of the activities incidental thereto."

An examination of the accounts of the Alaska Railroad was reported[52] to the Interstate Commerce Commission on August 31, 1930, by Examiner Leroy S. Price, which is of interest. He reveals the fact that there had never been an audit of the accounts of the Alaska Railroad other than "intermittent and irregular audits of cash in the hands of the disbursing clerk at Anchorage," and finally concludes, "not until the accounts are stated at their true value can the government know the cash outlay in the Alaska Railroad."

The losses assumed by the Government on account of the Federal operation of the railroads during the World War are estimated at $1 120 000 000. Losses due to the Emergency Fleet Corporation appear to have exceeded $2 000 000 000. The operating losses of the United States Shipping Board for the eight years, 1922 to 1929, were in excess of $220 000 000.

The Muscle Shoals Plant on the Tennessee River cost more than $127 000 000, of which approximately $40 000 000 was spent on electric power development.

---

[49] Senate Rept. 1230, 71st Cong., 3d Session.

[50] *Loc. cit.*, p. 3, Second paragraph.

[51] *Loc. cit.*, 71st Cong., 3d Session, p. 6.

[52] *Loc. cit.*, p. 20.

The project was built primarily for the manufacture of nitrates. The nitrate plants were not completed until the war was ended. The first plant proved impractical; the second was given a trial run of two weeks in 1919 after which it was closed and held as a stand-by plant. Obsolescence has probably been very great on a plant built for such a special purpose as this one, in the eighteen years in which it has stood idle.

The Inland Waterways Corporation is owned and controlled by the United States through the Secretary of the Treasury in whose name all the stock was subscribed. This Corporation operates the Federal Barge Lines on the Mississippi, Illinois, and Missouri Rivers, and from New Orleans, La., to Bingamport, Ala., *via* Mississippi Sound and Black and Warrior Rivers, and through stock ownership controls a railroad known as the Warrior River Terminal Company.

From 1924 to 1935 the system as a whole shows an average tonnage moved of approximately 1 500 000 per year. During the twelve years the system net revenue from operations was only $1 003 000, and the net income, $307 865. The total investment in real property and equipment used exclusively by this Government agency in transportation is $23 500 000. There appear to have been adequate allowances for depreciation of floating and harbor equipment in all years. It will be noted that there is not enough return reported over the twelve-year period to pay even a low rate of interest for a single year on plant actually used in transportation, and nothing at all in the way of recompense to the Government for work done on river and harbor improvement. The property pays practically no taxes and nothing appears as a deduction from earnings for interest on the investment in property and plant used. Had such a deduction been made to represent the actual interest paid by the Government and passed on to the taxpayers, net income would be shown between $6 000 000 and $7 000 000 "in the red." The story of this enterprise, in detail, furnishes material for an interesting paper.

The Test of Engineering Economics

The foregoing partial roll call of Federal and State projects in which Government has entered into business especially in times of emergency, causes one who has studied the statistical history of the projects to be decidedly pessimistic as to the outcome of the many and large projects which the Government has undertaken during the past four years.

It will probably be argued that private ownership has had many failures. That is true. There have been hundreds of cases of ill-advised, poorly planned, and badly or dishonestly managed private business undertakings that have resulted in complete failure and the loss of the entire investment. There is a long and unenviable record of privately owned railroads and utilities in which all thought of service was lost, and financial gain alone was the objective of promoters. There are chapters in the history of the railroads, of irrigation, or water-works, and of the electric industry that are scandalous and that gave ample cause for the development of regulation. The answer is that all the money that was lost in the failure of privately owned projects was the money of the individual investors, and the evils of management can be, and should be, cured by Government regulation. Just as soon as uniformity of accounting and full publicity of accounting and statistics were required of the railroads and real power was given to the Commissions, all the abuses and evils of a generation ago were abolished.

Regulation of private enterprise to prevent improper financing, discrimination of all kinds, rebating, or giving of subsidies, and excessive charges or deficient service is a true and legitimate function of Government that has proved its worth in the last fifty years.

One issue that is clearly raised by the great construction program of the present day is that of national policy. Should the people of the United States continue to favor individual initiative, enterprise, and opportunity regulated by law, or should they adopt a policy of nationalization of utilities and ultimately bring all industry and labor under the control of Government? That is for the nation to decide.

Another question that must be answered deals with the character of public work which should properly be undertaken in an emergency, such as that of 1933 which amounted almost to national paralysis. Millions of men were out of work. One of the great problems was to find work which, promptly and quickly, would furnish labor for the greatest number. Does the adoption of such projects as Bonneville, Grand Coulee, Tennessee Valley, and the many other long-time projects (which require from four to eight or ten years to complete) solve the emergency employment requirement? Or would not just as much employment have been furnished, and just as much steel, cement, and other structural material have been used had there been adopted some such a project as the building of safe and adequate bridges and railroad grade separations on all Federal highways.

In one case there is the planning of a single great structure and the organization of a single force of men for long-time employment. In the other case there is the planning of many structures in each State and the organization of many different construction forces in all parts of the country under the supervision of established highway commissions.

In one case the taxpayers of the nation pay in the end for the entire cost of some of the projects. In the other case, they pay it all, but they would get the lasting benefit of work, which in some of the States would be delayed for years, but which is a direct benefit to public transportation.

The writer believes that in passing upon whether or not any of these great projects are economically wise each one must be judged on its own merits, and all argument that it was an emergency undertaking must be disregarded.

Passamaquoddy certainly cannot qualify as an economic project. There is no demand for power at that location. If there were such a demand the economic answer would be to build a steam plant for $6 000 000 or $7 000 000 instead of the proposed tidal plant for ten times as much.

The extensive evidence that was secured by the U. S. Corps of Engineers in its study of the Columbia River seems to show that the bringing into cultivation of more than a million acres of additional farm land is not a present urgent need, that it could only be justified by the sale of vastly more power than can be absorbed by the territory for several decades in order to subsidize irrigation, and that there exists an engineering report to the effect that the area in question can be irrigated by gravity for less money.

Bonneville, were it alone being built, appears to be a reasonable project with good prospects of being self-liquidating. The one great question involved in that case is that of national policy; and the precedent of the Hoover Dam, designed and commenced during a Republican Administration, cannot be overlooked in considering it.

The policy of Federal improvement of waterways is of long standing. No one can question the propriety of spending money for navigation on streams such as the Ohio and Lower Mississippi which have been main arteries of traffic over the life of the nation; but to spend a quarter of a billion dollars on such a river as the Missouri which has no traffic, and has never had any worth the name, raises another question.

Can the nation afford to increase its burden of national debt at a time when every effort should be made to eliminate unnecessary expense and balance the budget, and in addition increase its annual expenditure for fixed charges, maintenance, and operation by more than $10 000 000 per yr, in the hope that a future water-borne traffic can be developed?

The writer thinks that the answer is "No," but wishes to remind readers that this problem was created by the Republican party.

The entire discussion comes down to a question of engineering economics. Putting to one side all argument as to whether Government ownership is wise or unsound, it would appear to the writer that the general policy that should control the adoption of any program of public works which involves the entry of the Government into any form of business or public service, whether in time of emergency, or not, should be determined by the Congress only, and not delegated to any bureau or commission for final decision.

No such project can be economically sound unless it can earn all operating expenses, including: (1) All cost of maintenance and upkeep of plant; (2) a reasonable allowance for a reserve to replace structures and equipment as they wear out; (3) interest on every dollar of the national debt incurred by the construction of the plant; and (4) a reasonable allowance for amortizing that debt over a period of forty to sixty years. The determination of these facts is an engineering problem. Therefore, no project should be undertaken without an exhaustive study of construction features, and market for the output, by qualified engineers reporting to the Congress. No better example of such a study can be found than that on the Columbia River made by the Corps of Engineers after four years of study.

Every such report should be a matter of record available to the public. There must be scores of reports of highly qualified engineering commissions, such as, for example, the PWA reports on Passamaquoddy, the estimate and recommendation of the Corps of Engineers, and the later report of the Special Engineering Board on the same project, on file in Washington, none of which has been made available to the public.

Allocation of funds was made for the Grand Coulee project in the face of adverse reports by the Chief of Engineers of the U. S. Army, the Board of Engineers of Rivers and Harbors, the Division Engineer, and the bitterly adverse argument of the Secretary of Agriculture. This was done without any guaranty of revenue notwithstanding the fact that the Chief Engineer of the Bureau of Reclamation, under date of January 7, 1932, submitted to the Commissioner of Reclamation the following perfectly definite recommendation:[53]

> "9. No construction on the Columbia River Dam and power plant should be undertaken until the contracts are executed for the sale of power which will insure sufficient revenue for annual expenses and the repayment of the investment in the dam and power plant with interest at 4 per cent within fifty years.
>
> "10. No construction on the irrigation development should be undertaken until the power revenues are assured and a suitable contract for the repayment of the investment in irrigation works within 40 years had been executed."

Every railroad, and practically every privately owned public utility, is required to keep all its accounts under rigidly prescribed classifications issued by Federal or State commissions, and to keep accurately and make public all pertinent statistics. This is as it should be. This requirement has bared many bad practices and made their abolition possible. Unfortunately, no such requirement applies to publicly owned utilities, either Federal or municipal.

In a recent article Arthur E. Morgan, M. Am. Soc. C. E., states:[54]

> "Under any method there are certain proprieties and decencies of government which should be observed. Where the public has invited private capital to supply an essential public service, there should be no capricious arbitrariness in destruction of duplication of facilities to the loss of honest, necessary and useful investment. Where bad government or lax administration has allowed inflated securities to be sold to innocent investors the public is not without responsibility. In case public power is used as a 'yardstick' or as a measure of what the private power industry should charge for its services, then it is imperative that records and accounts be honest and fair and open, and that there be no hidden element of subsidy. The very fundamental element of such comparison is honesty, fairness and openness in measurement. Take away those characteristics, and the supposed comparison may becloud the issue rather than clarify it."

It does not appear unreasonable to insist that every publicly owned utility be required to use exactly the same accounting rules and statistical data that are required of similar privately owned utilities. This is of as much importance to the Congress and the Administration as it is to the public.

CONCLUSIONS

Twenty-four hundred years ago Pericles made the statement that "acts are foredoomed to failure that are undertaken without discussion." That is just as true to-day as it was before the Christian era.

Who should do the discussing? The Congress, in American Government, is vested with the authority to represent the taxpayers and decide which expenditures are wise and which are not.

Disregarding all the earlier discussions of the Panama Canal and Nicaragua Canal routes between 1870 and 1875 prior to the French activities, the Congress began active discussion of the Panama Canal in 1899, and in March,

---

[53] Rept. of U. S. Bureau of Reclamation, H. R. Doc. No. 103, 73d Cong., 2d Session, pp. 484–485.

[54] "Public Ownership of Power," by Arthur E. Morgan, *Atlantic Monthly*, September, 1937, p. 342.

1903, passed the Act which authorized the President to negotiate with the Republic of Panama. Not until December, 1903, were negotiations completed. Then came the long discussion as to whether a lock canal or a sea-level canal should be built, ending with the adoption by Congress in 1906 of the lock canal. The actual construction cost of this project was $336 400 000. When the $40 000 000 paid to the French Company, and the $10 000 000 paid to the Republic of Panama are added, the total cost reached $386 400 000, practically $30 000 000 less than the estimate of the Grand Coulee project.

This great canal had the benefit of years of study by a number of the greatest engineers of the time. There was no undue haste. Great questions were not settled by individuals or bureau heads. The records of the Congress show that all questions of general policy, even to deciding the engineering question as to whether the canal should be a lock canal or a sea-level canal, were submitted to and decided by the Congress. The decision was based on the recommendation of the engineers.

If policy has changed; if individuals or bureaus are to authorize expenditures of many hundreds of millions of dollars without Congressional approval, or are allowed to change contracts by the issuance of departmental orders, thereby changing the entire character and objective of the project, is it not time for members of the Engineering Profession to break silence?

The writer believes that those members of the profession whose hands are not tied, who are free to tell the facts, should do so freely and should discuss the economics involved as well as the technical features of public works.

Conditions in the United States to-day call for "hard-headed" economy, for the careful analysis of every proposal to spend money raised by taxation, and for the firm rejection of every one that is not economically sound.

Members of the Engineering Profession, better perhaps than any one else, can advise the people of the United States as to the economic soundness of proposals to spend vast sums on public works, especially those designed to render public service of a kind that should make the project self-liquidating.

They will fail in their duty if they keep silence.

AN APPEAL TO REASON

By William J. Wilgus,[55] Hon. M. Am. Soc. C. E.

Synopsis

In this paper, the writer wishes to avoid the impression that he disbelieves in the creation of worth-while public works of the type considered in this Symposium. In the words of the Hon. George D. Aiken,[56] Governor of Vermont:

> "I hold no brief for any private utility corporation. I even hold that through their manipulations in pyramiding values [too often fraudulent] and the acquiring of unearned and unwarranted profits at the consumer's expense, they are largely, if not principally, responsible for the present state of affairs."

The bracketed comment is by the writer. Neither does the writer hold with those who would maintain the unemployed in corrosive idleness, destructive of all that is best in American life, rather than at self-respecting work, at a somewhat greater expense, from which the public gains material and spiritual returns. The work, in fact, must be worth while in the public interest and not uneconomic and wasteful, involving a tragic loss of public monies for ever-continuing interest charges and upkeep.

Worth-while public works need not necessarily suffer from the evils of corrupt, incompetent political management. There are notable examples of admirably run publicly owned water-works, highly successful and well operated municipal electric plants, toll tunnels and bridges and the other commercial activities, such as those of the Port of New York Authority, the revenue-producing enterprises operated under the auspices of the New York City Park Department, and various toll-bridge authorities in New York City, and the publicly owned transit facilities in the same municipality which eventually are to be expanded by the addition en masse of its privately owned subways and elevated lines. There are, too, many city managerships to be looked to as outstanding examples of successful administration; this can likewise be said of many works under the jurisdiction of the U. S. Army Engineers. Under proper safeguards and conditions, it is possible to run public enterprises with honesty, competence, and resourcefulness, coupled with a strict observance of proper accounting at all times open to the public. The quicker the people realize this and prepare for it, the better off this country will be. To drift blindly, without a chart or compass for guidance, will mean the continuation of the ills of public management, vastly to be multiplied, as private utilities, whether one likes it or not, come more and more under public control. With the public ownership of railways and other utilities "in the offing," it behooves the civil engineer to abandon a King Canute-like attitude of negation and to favor a constructive course leading to a reasonably satisfactory conclusion.

---

[55] Weathersfield, Vt.

[56] Address at Plymouth, Vt., August 8, 1937, reported in *Rutland (Vt.) Herald*, August 9, 1937.

It is deeply to be regretted, therefore, that the gargantuan projects analyzed in this Symposium have been promoted by the Government without at the same time offering evidence that they hold promise, within a reasonable time, of becoming socially and economically justifiable under efficient management.

MAJOR PROJECTS

In the Passamaquoddy Tidal Power Project, the estimates of cost have ranged widely from $37 000 000 to $62 000 000, to which must be added unknown sums of magnitude for distribution systems and for interest, and other carrying charges, until the project, if ever, shall become self-supporting. It would also appear that the intended dual methods of operation—by water power and by coal or oil—will result in an absurdly high cost per unit of capacity; and there is no market for the power in sight. Furthermore, it is said that certain engineering reports on the project have been withheld from the public. As so far revealed, it is not a "pretty" story, especially in view of the threat that workers in the coal and oil fields, and in the transportation industry, are to be made to suffer to the extent that water power thus is to be wastefully used.

As to the Fort Peck Dam, the estimate of cost has risen from $86 000 000 to $108 000 000, for which the resulting improvement in the low-water flow in the Missouri River will bring a grossly inadequate return to the public. It may be that in some unexplained manner the improved river channel is expected, within a reasonable time, to afford a water outlet for the products of the Northwest at savings in the cost of transportation sufficient to offset the added interest charges, the expense of upkeep to be borne by the people of the country at large; or, it may be that other benefits worth the price are to be expected by the public in the way of flood control, improved sanitation, cheap power, and the reclamation of waste lands. The evidence, however, appears to be lacking.

Likewise, the estimated cost of the Grand Coulee project in the Columbia River Basin has risen from $108 000 000 to upward of $437 000 000 for the combined purposes of navigation, power, and irrigation, to which must be added the first cost of needed distributing systems and auxiliary structures of magnitude, as well as the annual costs of depreciation, maintenance, operation, and interest on the capital cost, from the time of completion of the project until it shall perchance become fully self-supporting in the uncertain future. In this, as well as in the case of the Fort Peck Project, the claim is to be borne in mind that already there is a superabundance of irrigated lands in the West needing competent settlers in large numbers to make them an economic success.

JUSTIFICATION OF FORESIGHT

In total, the present estimated cost of these three outstanding projects is upward of $600 000 000, plus the unfigured enormous additional costs due to contingent expense and operation. In judging their merits or demerits from the economic angle it seems necessary to use caution. Vision—or, perhaps, prophecy—has been the moving cause from which some of the world's most notable products of the brain and the hand of Man have come forth. Witness, for instance, the Canadian Pacific Railway, built by men of vision across plains and mountains then unpeopled and undeveloped, with buffalo bones at first as the only freight in sight. The electrified Grand Central Terminal, in New York, N. Y., may also be pointed to as an example of imagination come true, with its rich by-products gained through the utilization of air rights, initiated in the face of forebodings that offices in that region could not be rented in competition with the established down-town Wall Street district; that guests would not patronize hotels and apartments over or neighboring a smoky, dingy, noisy railroad station; that cabs, then horsedrawn, with their attendant odors, could not be parked underground; and that vehicular travel could not be diverted from Fifth Avenue to Madison and Park Avenues, nor to the intended elevated driveways around the station. A vision of the future, bearing directly on this subject, may be quoted from a report issued,[57] in 1937, by the National Resources Committee:

> "Another material (than manganese) which is essential to the production of alloy steels, as well as for a coating metal, is chromium. It also is largely produced from foreign ores. There is a recently developed Bureau of Mines process for producing ferrochrome electrolytically from chromite ore. There is still considerable developmental work to be done on this, but if it proves feasible it will very likely be a practical outlet for the power to be produced at the Grand Coulee Dam. A new ore deposit of very significant size has recently been opened up in the Philippines and contains about 35 per cent of chromium oxide. It would be feasible to ship this material to the Columbia River water-head for electrolytic recovery of ferrochrome. There are also considerable deposits of this same type of ore in Montana and one county in Wyoming, which would be available in case of need."

Other possible developments in electro-metallurgy in the field of such metals as aluminum, magnesium, manganese, and iron, are pointed to in the same report, as well as the possible creation of new manufacturing centers convenient to sources of raw materials and a consuming public, and the reclamation of waste lands for the purposes of agriculture.

WISHFUL THINKING VERSUS FORESIGHT

These are only hints of what may "come out of the blue" when new conditions are created, such as improved channels for transportation, changes of motive power, and pools of cheap power of huge proportions accessible to ocean vessels. Wishful thinking or idle guessing should carry no weight in prophesying what new developments may cause the Passamaquoddy, Fort Peck, and Grand Coulee Projects to be economically justifiable. Civil engineers have a right to ask just what line of reasoning in this respect has guided their Government, so that an intelligent conclusion may be reached as to its soundness, and the total carrying charges—interest and upkeep—that necessarily must be borne by the people of the United States before the project in each instance shall, perhaps, become self-supporting.

---

[57] Rept. on Technological Trends and National Policy, by the National Resources Committee, 1937, p. 357.

In a word, then, there is reason to demand: (1) A defense, if one is possible, of the original committal of the people of the United States to projects based on the promoters' "half-baked" plans in connection with which the estimated costs later have been found to be far too low; (2) an explanation of the excessively high cost per unit of capacity or development that characterizes many of the projects; (3) reasonably accurate estimates of cost inclusive of all elements of every nature; (4) an outline of the reasoning, with data, in support of the alleged economic justification of each of the projects; and (5) a disclosure of the engineering and other reports and opinions hitherto held *en camera* pertaining to some present Federal projects.

FLORIDA SHIP CANAL

It is not alone to the three major projects at Passamaquoddy Bay, Fort Peck, and Grand Coulee (for knowledge of which the writer is indebted to Professor Riggs' paper) that this paper is confined. The writer has also had occasion to familiarize himself with the Government's Florida Ship Canal project, which, in many of its aspects, is even more forbidding.

Basic Considerations.—The Peninsula of Florida, about 95 miles wide at its narrowest point, projects (with its terminating arc of islands) about 440 miles south and southwest to Key West and beyond, bounded by the Atlantic Ocean on its east, and the Gulf of Mexico on its west. The Straits of Florida, on its south and southeast, extend about 250 miles to the Island of Cuba and 40 miles to the Bahama Banks, with a minimum depth of 1 000 ft. Generally low in altitude, the backbone or central axis of Florida, for a width of 40 to 50 miles, rises to elevations of from 100 to 200 ft above sea level with a few heights or knobs rising to 300 ft and one to an elevation of 325 ft.

Underlying the Peninsula is the porous Ocala limestone formation, honeycombed with caverns and intricate channels of unknown location, number, and size, and dipping from north to south to levels far below sea level. On the flanks of this rock formation, to a greater or less degree, a comparatively impervious material is superimposed except at two eroded areas on the backbone of the State which act as catchments for the rain that there descends into and permeates the limestone cavities and, as fresh water, flows upward under pressure through artesian wells and at breaks at lakes and springs, and in the open sea. The northerly of these eroded areas, roughly 50 miles wide and 120 miles long, is separated from the one on the south by a low-lying saddle, about 100 ft above the sea, centering at Ocala, Fla., about 75 miles below the latitude of Jacksonville, Fla., on the Saint Johns River. Draining eastward from this saddle are the waters of the Oklawaha River emptying into the Saint Johns River near Palatka, Fla., flowing northward and eastward to the Atlantic Ocean, and westward the waters of the Withlacoochee River, emptying into the Gulf about 94 miles north of Tampa Bay. The fresh water in profusion thus under pressure beneath the Peninsula is vital to the culture of citrus fruits and vegetables, and the attraction of visitors from the North, on which the people of the State depend for their livelihood. This fact, as will be seen, is first to be borne in mind in giving study to the Florida Ship Canal problem.

Along with this is to be viewed the effect of the Peninsula on the time consumed by water-borne commerce in passing between the Gulf of Mexico and the Atlantic Coast, and foreign countries, through the Straits of Florida. Since the number has steadily increased in recent years, it is estimated that in 1935 as many as 12 000 vessels carrying more than 60 000 000 short tons were engaged in this service, principally in the movement of petroleum products, of which about 80% or 90%, it is variously claimed, is to be considered in weighing the pros and cons of a short-cut across the State.

History of Engineering Analyses.—In the 1920's the growing desire to shorten the journey between the Gulf of Mexico and the Atlantic led to various surveys by the Corps of Engineers, U. S. Army, for a barge canal connecting the Atlantic and Gulf intra-coastal protected waterways, and in the early years of the present decade for that as well as an alternate ship canal. A series of reports then ensued, eight in all, in which the 9-ft barge canal project was ignored or disapproved, and the ship canal of differing designs and estimates was in some instances approved and in others disapproved.

In all these reports the adopted general course of the proposed ship canal has been the same, running, as it does, westerly and southerly in the Saint Johns River from deep water off its mouth in the Atlantic Ocean for about 78 miles, past Jacksonville, to Palatka; thence, southwesterly and westerly in the valleys of the Oklawaha and Withlacoochee Rivers to the Gulf coast, in a 95-mile artificial cut of earth and rock having a maximum depth of 141 ft or more as recommended in the later reports; and thence, for from 25 to 27 miles in the rock-underlaid shoal waters of the Gulf to deep water, a total length of nearly 200 miles. Thus would be provided, it is claimed,[58] "a route between the Gulf and the Atlantic seaboard from 300 to 350 nautical miles shorter than the present route around its [Florida's] southern end," and a saving of "somewhat less than one day's steaming time."

It is the notching of the lip of the ground-water reservoir by this deep cut at the edge of the northerly catchment area to which reference has been made, that has given rise to the fear that the resultant lowering of the head in artesian wells and springs in many parts of the State will permit salt water to rise and cause damage to fruit and vegetable culture and seriously affect lake levels and municipal water supplies.

The first of these reports, a preliminary one made at the instance of the President by a Special Board of Army Engineers, June 3, 1933, was intended for the use of the engineers of the Reconstruction Finance Corporation and was not made public. The recommendation in a second report, made by the engineers of the Public Works Administration (PWA), October 19, 1933 (in connection with an application of the Ship Canal Authority of the State of Florida for a public loan of $115 000 000 to cover the estimated cost of a toll 30-ft lock canal), was not approved by the PWA Administrator, and failed of action.

The third report, made by a Special Board of Army Engineers, December 30, 1933, placed the cost of a 35-ft lock canal, with a minimum channel width of 250 ft, at $199 481 000 plus $8 562 000 for land and damages, a total of $208 043 000, exclusive of interest charges during construction. This report, at the request of local interests favorable to the enterprise, was not made public until three years later, after work had been started on the canal, when it developed that its verdict had been adverse to the economic justification of the project at this time, as had been the findings of the Shipping Industry contained in a report made by the Department of Commerce on February 1, 1934.

---

[58] Committee Print on "Atlantic-Gulf Ship Canal, Fla.," 75th Cong., 1st Session, pp. 2, 3, and 28, respectively.

The fourth and fifth reports were made by the President's Interdepartmental Board of Review on June 28 and September 15, 1934, respectively, which estimated the cost of a 30-ft sea-level canal, with a minimum channel width of 250 ft, at $142 700 000, exclusive of interest charges, and $159 834 000, inclusive of interest, plus $3 000 000 for rights of way to be borne by local interests. The project was declared to be not self-liquidating by tolls collected from shipping, the annual charges being placed at $7 250 000 and the estimated benefits at $7 500 000, which was too close to finance the project on that basis. In the following January the PWA reached the same adverse conclusion as had been the verdict contained in the report of the Department of Commerce a year before. Nevertheless, the President, on August 30, 1935, allocated $5 400 000 from the Emergency Relief Fund for starting the work, in addition to which money for acquiring the necessary rights of way was provided by the Florida Ship Canal Navigation District, created by the State Legislature. Apparently, from then on the project was to be considered as toll free to all users, foreign and domestic.

The sixth report was made by the Revisory Board of Army Engineers, on November 1, 1936, after the relief allotment had been exhausted, in which the estimated cost of a 33-ft sea-level canal, with a minimum channel width of 250 ft, was placed at $162 985 000, exclusive of interest charges, or $185 471 000, inclusive of interest charges, and of $3 000 000 to be borne by local interests for rights of way, damages, etc. The project was declared to be economically justifiable, a verdict arrived at by calculating annual savings in ship-operating expenses, interest on ship cargo, freight rates, and navigation hazards plus recreational value to pleasure craft at $9 553 244, and annual net carrying charges at $8 242 969, leaving an alleged net annual gain of $1 310 275, which was held to show that the project was economically justifiable on a toll-free basis. The latter figure, however, would not in its entirety accrue to American interests. In the estimated savings ($9 553 244) is included the value of savings in ship time and interest on cargo ($7 155 720) of which 20% (amounting to $1 431 144) should be enjoyed by vessels flying foreign flags. This would leave annual savings of only $8 122 100 for the benefit of American citizens, in contrast with the annual carrying charges amounting to $8 242 969. On this showing the project is not economically justifiable, even granting that the benefits flowing to private interests in some manner really would be passed on to the public called upon to pay the bill.

Then came the long deferred hearings before the Board of Engineers for Rivers and Harbors late in December, 1936, without which in the usual course the project could not be considered by Congress for approval or disapproval.

This resulted in the report of the Board on February 24, 1937—the seventh in this series—fixing the estimated cost of a 35-ft sea-level canal, in preference to a shallower one, with a minimum channel width of 400 ft, at the sum of $263 838 000, exclusive of interest charges (computed at $25 005 000), and exclusive of $3 000 000 for right of way to be paid for by local interests. The total cost to all interests, therefore, was placed at $291 843 000, in which provision is made for the removal of nearly a billion cubic yards of earth and rock. In this estimate, as in all the others, nothing was included for consequential damages resulting from disturbances of the underground water supply. As bearing on this the Board stated:

> "In view of the undeterminable possibility that the excavation of a sea-level canal might open underground channels in the Ocala limestone of such size and extent as would drain a wide area, with consequent extensive damage to ground-water supplies, any authorization for the construction of the canal should empower the Secretary of War, on the recommendation of the Chief of Engineers, to modify the plans to provide for the construction of a lock canal if at any time during the progress of the work such a modification should be found warranted in the interest of protecting the ground-water supply."

No estimate, in such an event, was named for the additional cost of making the change, nor for claims for indirect damages which, according to the Board, the Federal Government under the law would face the onus of meeting. The Board declared that the benefits to be reaped from such a canal "do not establish economic justification for the large expenditures necessary for its construction," this conclusion having been predicated on estimated annual charges of $14 930 000 and benefits or savings of $8 543 000, leaving an annual net loss of $6 387 000 apart from diversions of benefits to vessels flying foreign flags.

Then came an eighth report—that of the Chief of Engineers on April 1, 1937—disagreeing in large part with the recommendations of the Board of Engineers for Rivers and Harbors. The Chief of Engineers estimated the cost of a 33-ft sea-level canal, with a 400-ft minimum width of channel, at $197 921 000, apparently exclusive of interest charges (or $215 735 000 including them), plus $3 000 000 for right of way to be borne by local interests, a total of $218 735 000 in contrast with the aforementioned Board's estimate of $291 843 600 for corresponding items applicable to a canal 2 ft deeper required, in its opinion, for safety. The Chief of Engineers does not "share the apprehension expressed in the report of the Board of Engineers, as to the possible adverse effect [of a sea-level canal] on ground-water supplies." He places the annual charges against the United States and Florida at $8 905 000 and the benefits to shipping at $8 741 000, or practically a stand-off of what the writer considers private gains at public expense. Making allowance for the portion of these benefits that would flow to vessels flying foreign flags, the result would be even more painful to the people of the United States.

Conclusions from Available Data.—At this point it should be remarked that, for some mysterious reason, the item of interest charges during construction, in the Government estimates, is treated as a thing apart, to be ignored in giving the public an impression of the total cost of the project. Hire of money, termed interest, is, of course, just as much an element of cost to be borne by the taxpayer, as hire of labor or costs of material. To omit it from the total estimates is in this respect to misguide the public.

It will be seen that the estimated costs of the project, to the Federal Government and Florida "interests," have varied from a low of $115 000 000 to a recent high of nearly $300 000 000, equal in amount per ship-mile saved to many times that incurred at the Panama and Suez Canals, to which is to be added the cost of damage arising from "possible" injury to the ground-waters of Florida and the added cost incident to the changing of the canal from sea-level to a lock design in case the later discovered certainty of such injury would make that course necessary.

Whether or not the net benefits to be gained from this vast and uncertain expenditure make the enterprise justifiable from a self-liquidating or economic standpoint has been open to a variety of opinions. The answer is "yes" on the part of the Revisory Board in 1936 and the Chief of Engineers in 1937. It is "no" on the part of the Special Board of Army Engineers in 1933, the shipping industry as reported by the Department of Commerce in 1934, the President's Interdepartmental Board of Review in 1934, the Administrator of PWA in 1935, and the Board of Engineers for Rivers and Harbors in 1937.

Such a jug-handled arrangement whereby the beneficiaries of the canal, domestic and foreign, are to be free to keep their savings while the taxpayers —that is the people—"foot the bills" of undefined magnitude, has an even more repugnant look when it is understood that by the time the canal should be completed in six or more years, it would run the risk of being already obsolete and unused.

In viewing this aspect of the situation, it is well to bear in mind that the margin of saving in steaming distance *via* the proposed Florida Canal is very slight in comparison with that enjoyed *via* the world's existing great ship canals. In the case of the Suez Canal, the saving over its Cape of Good Hope rival is, say, 40 times its length of 100 miles; and in the case of the Panama Canal the saving over its Cape Horn and Cape of Good Hope rivals is, say, 100 to 200 times its length of 50 miles. Both are in sharp contrast with the Florida Canal's saving over its Florida Straits rival of less than two times its length of 200 miles. The two cape routes are hopelessly out-distanced by the interoceanic cut-offs with which they have to cope. The Florida Straits route, on the other hand, is not so handicapped and through improvements in vessel design, and a less hazardous course, has every prospect of "holding its own," for reasons on which it may be well to touch.

The estimated saving in ship time through the use of the proposed Florida Canal as against the Straits of Florida (22 hr) is based on a difference of vessel speeds *via* the two routes which will become less and less as progress is made in the art of shipbuilding. The Chairman of the U. S. Maritime Commission recently has stated[59] that "the United States is third in world tonnage (mostly obsolete), fifth in speed of ships, and eighth in ranking of modern ships in operation." With an increase of 50% in the speed capacity of vessels, already said to have been realized in the mercantile fleets of foreign countries with which the United States must compete, there will be no appreciable saving in time to be made through the use of the proposed shorter canal route in which advantage may not be taken of modern open-sea speeds. Even under present conditions many of the steamship companies now navigating the Straits of Florida assert that, despite its intended absence of tolls, they will not use the canal, if built, because of higher insurance premiums on hulls and cargo passing through the canal, and[58] "the hazard of damage by collision or grounding in the constricted waters of the canal" which the Board of Engineers for Rivers and Harbors considers "would greatly exceed the hazard of damage in the open waters of the Florida Straits including damage and delays due to hurricanes in the latter."

---

[59] Reported in *New York Times* in dispatch from Washington, D. C., August 16, 1937.

In a word, unlike the Panama and Suez Canals and unlike other artificial waterways having no alternative routes to threaten their use, the proposed Florida Canal would ever face the prospect of the continued use of a competitor having lesser handicaps and the superior advantages of open-sea navigation. The margin of saving in time *via* the new route is too slight to warrant an expenditure upon it of $200 000 000 or $300 000 000, or more, which the people never can "get back," to quote the words of the President who is reported to have named this as a condition.[58]

From what has been stated herein[58] in respect to the toll-free Florida Ship Canal project the situation may be summarized as follows:

(1) The estimated cost of the project has risen in the four years, 1933 to 1937, from $115 000 000 to as high as $291 843 000, with the assurance of a marked increase, of unknown size, should a change be found necessary from a sea-level to a lock design, and should consequential damages be incurred through injury to the underground water supply of Florida;

(2) The estimated carrying charges to be borne in this connection by the people of the United States have risen in the same period from $7 250 000 to as high as $14 930 000 per yr, also with the assurance of a marked increase should the aforementioned conditions prevail;

(3) The estimated benefits to be enjoyed by the users of the canal and its other beneficiaries—foreign and domestic—have ranged from a low of $7 500 000 to a high of $9 553 244 per yr, constituting in effect a public subsidy to private interests from which the people of the United States as a whole would gain nothing whatever, other than the possibility of some lowering of freight charges of unknown extent, of which there is, to say the least, a doubtful chance when competition rather than cost of service is what governs the fixing of rates;

(4) In thus failing so signally to show benefits in excess of carrying charges, the canal project falls far short of meeting the condition laid down by the President that, to have his approval, it should in effect bring to the people of the United States the assurance that they would get their money back;

(5) The possibility of grave injury to the underground water supply of Florida, through the building of a sea-level canal, is one to be viewed with concern by the people of the State and nation. It is comparable to a community, informed that an important bridge on which the people depended for access to the world might fail, with resulting death or injury to their families

—a case in which to doubt is to condemn; where there are no compensating advantages to offset the risks;

(6) The disruption of Florida's highway system along the canal, involving the creation of needed future crossings at the expense of the State, also to be burdened with the inconvenience and cost of upkeep and operation of highway ferries and drawbridges as well as the costs of rights of way and other lands for the canal; the cost of appropriate terminal and transfer facilities; and, the cost of maintenance and operation of the canal in excess of a fixed annual sum to be borne by the Federal Government, should the recommendation of the Revisory Board in this respect be endorsed by Congress, are all matters of great moment to the taxpayers of that State in which, too, sight is not to be lost of threatened injury to its wild life; and,

(7) The modernizing of the country's merchant marine, about to be undertaken, will result in the employment of speedier vessels in the Gulf-Atlantic trade and, in consequence, the continued use of the safer present open-sea route around the tip of Florida as against the canal route then offering no substantial saving in time and greater dangers of navigation, thereby threatening the canal, if built, with early obsolescence, even if the exhaustion of oil fields tributary to the Gulf is long postponed.

Recommendations.—In view of the foregoing conclusions, therefore, the Florida Ship Canal project, as a substitute for, or rival of, the existing open-sea route through the Straits of Florida, is without a single sound argument in its favor, and should not receive the stamp of approval by Congress, accompanied by appropriations for its continuance. It is better thus to abandon what was started as a relief measure at a cost of $5 400 000 of Federal money and an unknown sum thus far expended by local interests for right of way, than to throw good money after bad.

In taking this stand against the financing of useless public works it is not meant, of course, that Federal funds should not be devoted to the construction of really worth-while projects in order to give work to the unemployed. On the contrary, the money saved from loss on uneconomic enterprises like the Florida Ship Canal may, and should, be devoted to the supplying of such crying needs as added public thoroughfares for a rapidly growing automobile traffic. For instance, the building of an International Parkway along the Appalachian Uplift, in co-operation with Canada, connecting many national and State parks and forests and other recreational areas, reaching from Montreal, and Quebec, Que., and the Gaspé Peninsula on the Gulf of St. Lawrence, to Key West, Fla., and other attractions on the Gulf of Mexico, would cost no more in the United States than a Florida Ship Canal; it would give employment to skilled and unskilled labor in seventeen States of the Union instead of one; it would serve to protect the mountain forests and streams from private spoliation and restore many of them to their original charm; and, from a social viewpoint, it would provide the public with a safe, convenient, and inspiring means of movement between the widely varying climates, scenes, customs, and fauna and flora of the North and South, free from commercial usage, billboards, and other objectionable features, in regions neighboring great industrial centers where utility and pleasure thereby would be sanely served in these days of increased leisure.

A CHALLENGE

The papers of the Symposium constitute a terrific arraignment of those who are entrusted by the people of the United States with the handling of their affairs. Great public works are declared on the record, to have been conceived in error. Can it be that the Engineering Profession is not in possession of all the facts with which to reach a just conclusion? If so, the Government's side should be presented without reserve. As citizens of a democracy, and as engineers qualified for the purpose by education and experience, the Civil Engineering Profession should, in the interest of the public, approach this question in a non-partisan spirit, searching only for the truth. In the words of Professor Riggs, "They will fail in their duty if they keep silence."

In the case of the Florida Ship Canal, as in the instances referred to by other authors of this Symposium, involving in all a possible expenditure of more than a billion dollars, it is to be hoped that their proponents—members of the Society and others—will draw attention to any errors of fact which, unintentionally, may have been introduced herein, and to any reasoning that they may care to offer in rebuttal. To arrive at the truth is the important objective, so that engineers may properly advise their fellow citizens who are not experienced in such matters. Thus will there be ground for hope that the hazards of uneconomic public works construction in the future will be avoided, or at least lessened. In that cause there can be no higher call to public duty.

ACKNOWLEDGMENT

In the preparation of this paper, in addition to other sources cited by footnote references, the writer has made liberal use of the factual data presented by Professor Riggs in this Symposium.

DISCUSSION

J. K. FINCH,[60] M. AM. SOC. C. E. (by letter).—Although few engineers would question the soundness and force of Mr. Fay's arguments for the future planning of public works, it is quite obvious that very great practical difficulties will be encountered in putting them into effect. There are clearly two major phases of this planning movement.

On the one hand, there is the necessity for foresight in planning public works—a need for engineers to encourage comprehensive planning rather than a hand-to-mouth practice in public construction if such works are to be better adapted to future public needs and requirements. In this respect they must recognize that many existing public works agencies are not set up to undertake such comprehensive planning effectively, and it is doubtful whether the fundamental changes in organization, tenure of office, etc., necessary to permit or to encourage the development of a long-range policy, can be effected. Apparently, the practical approach to the problem is not through reforms in existing public works agencies, but through setting up separate planning boards or commissions, which will be independent of changes in political party and will give particular attention to the longer range viewpoint. This movement is growing rapidly. City and regional planning boards are increasing in number. It was reported in 1935, for example, that there were forty-five State planning agencies, and many municipalities have city planning boards. The attack on this problem, therefore, has been through this more or less indirect plan—far from ideal, perhaps, and still, in many cases, lacking in implementation to make the movement fully effective—but apparently the most promising and practical line of attack yet developed.

On the other hand, the further proposal to use public works as a means of reducing the fluctuations in the construction industry, while fine in theory, seems discouragingly remote in the possibilities of achievement. It is dependent, of course, on the aforementioned future planning movement but, in addition, unless the United States abandons its democratic form of government, public opinion must, as it always has, continue to play an important part in the initiation of actual construction. There may be little difficulty in speeding up public construction in periods of depression as has been done in recent years, but the idea that the Government can retard public spending when prosperity is at its crest sounds well in theory but impossibly impracticable in practice. It might be hoped that the Government could have in hand some well planned and useful projects which can be undertaken in periods of depression, but, in all probability, the really pressing, and, therefore, most important, works will have been built when times were good and their construction was demanded by the public.

Turning to the papers by Messrs. Mead and Riggs, many readers would accept their statements of fact as to the false business economy, or, too frequently, total lack of such considerations, in the construction of the works described. Many engineers would also condemn in an equally forceful way the apparently deliberate suppression of the engineers' reports on these projects and the later attempt to place the onus for the initiation of these economically useless and imposingly wasteful expenditures on the engineer. Many engineers would also agree with Mr. Mead that the TVA "yardstick" notion is a political humbug, and a child of wishful thinking and bad bookkeeping—that, in fact, the entire recent Federal viewpoint on the power problem is unreasonable, economically destructive, and eminently unjust. At the same time, many engineers would not agree with the conclusion implied, at least, in these papers, to the effect that the Government should have nothing to do with any project involving power production and should build no works that are not fully justified from the standpoint of business economics.

---

[60] Renwick Prof. of Civ. Eng., and Director, Summer School of Surveying, Columbia Univ., New York, N. Y.

It seems quite obvious, for example, that the Federal Government is already involved in many projects in which the development of power is incidental (is a "contributory benefit," as the Supreme Court puts it) to works which are clearly within the constitutional scope and recognized function of modern government. The time is long since past when Government can limit its activities to the simple functions which constituted its entire scope of duties in Colonial days. The time has passed when the American people will turn over to private interests the remaining public property of the nation for exploitation and development by such interests and for private gain. It seems obvious that this nation has embarked, for better or for worse, on a policy involving the governmental development of its remaining public properties and resources in what it is hoped will be a wider public interest.

It would appear to the writer, therefore, to be futile and impracticable and thus hopelessly reactionary and completely unconstructive, to damn the present entirely and argue for a return of the "good old days." It is all very well to argue that one should not compromise with thieves and murderers, and it is apparently on this ground that the extremists of the New Deal refuse to listen to the power utilities and the power utilities refuse to compromise with the New Deal. To face the facts, however, one must admit that there are two interests both legitimately involved in the power field and, as in the case of capital and labor, these two interests, private and public, must get together, must reach some fair and just basis for co-operation, rather than continue a wasteful and unnecessary battle at the expense of the public. The present Federal viewpoint, if persisted in, will lead to economic suicide. The present public utility attitude often seems planned to alienate rather than woo public support. The engineer is generally considered to be a man of common sense, and he certainly cannot support the extremists on either side. While admitting much which both sides say, he will insist that a compromise is the only practical solution of the problem.

Much can be said, of course, on both sides of this question, and it will probably be necessary, in order to find a sane solution of the problem, to ignore rather than to attempt to reconcile some of the extremists if a compromise is to be effected. It is unquestionably true, for example, that a radical modification of the recent viewpoint of the Federal Administration is the first necessary move toward peace and co-operation. With the Federal Government going ahead with power developments in fields which private companies already serve, with public funds being used to construct municipal plants which put existing plants out of business, it is small wonder that the private utilities are up in arms and that billions in utility constructions are held up. This policy is destructive of economic values; it results in the waste of public funds, depletes the national income, and retards recovery. No engineer whose viewpoint is based on engineering principles rather than on blind bias and emotion can support such a policy.

On the other hand, few thoughtful engineers would attempt to defend the marking up of capitalization and other abuses in some of the power utilities which characterized the pre-depression years. These companies are granted a practical monopoly of an essential service and enjoy a relatively constant and steadily growing market. It seems clear that the lowest possible rates consistent with adequate service should be the goal of their operations. A low interest rate on a fair valuation is all that should be expected. Yet in the halcyon days before the depression the "merchants of debt" argued that capitalization should be marked up to the top figure which income could justify and, through holding companies and similar means, proceeded to burden some utilities with unnecessary and unjustified capital expense. The engineer must condemn with equal warmth this narrow, unsocial, and, in the long run, economically fatal and unconstructive policy. Clearly, if the public utilities take no steps to put their houses in order, and persist in fighting regulation by fair means or foul, the patience of the American people will ultimately be exhausted and the power business, like the water supply business, will be taken over by Government. In the long run, business must be conducted so as to advance the economic welfare of the nation and serve the public interest, if it is to survive.

The writer knows that Messrs. Mead and Riggs would condemn such utility practices and policy, but they apparently feel that this "public utility attitude" reflects the viewpoint of but a small part of the industry, whereas the present policies which have been advanced and encouraged by the New Deal forces are far more fundamental and dangerous to our national life. Although the writer would admit the force of this argument, when advanced by these experienced and careful analysts, it seems clear that the suggestions made in their papers, while directed toward the correction of an existing evil, cannot form the basis for a constructive and progressive general power policy. Co-operation seems essential. After all, it should be the purpose of both Government and business to advance and strengthen the national economic structure, because it is on this structure that our social and national development must rest. Clearly, the basic policy of both Government and business must be based on this principle and must reflect not a narrow, short-sighted opportunism but a reasonable and forward-looking viewpoint. Engineers are so accustomed to planning not for to-day but for to-morrow, of attempting to predict and to plan for future needs, that they assume that this is a common human trait. They evaluate a policy not solely on its immediate advantages but attempt also to picture its future effects. Unfortunately, this is not a common human trait—the world says "take the cash and let the credit go." A little more foresight in both business and political thinking and in the development of business and public works policies is an essential to the continued growth of American institutions. Accepting as a principle the basic idea that mutual understanding and co-operation on a sound economic basis are essential to the future usefulness and sane development of the power business, the writer is confident that engineers are capable of developing, with fairness and impartiality, the necessary details for such a working agreement.

Finally, those engineers who would adopt as a principle the idea that Government should not undertake to build any works except those which can be shown to be economically justified on a business basis, have apparently forgotten or ignored a basic principle of democratic Government. There are many public works which cannot be thus justified and, furthermore, the decision as to whether they should or should not be built is not a simple matter of engineering opinion. It is a question of public opinion. In short, what shall or shall not be done (within the wide limits of constitutional and other law) is determined solely by the state of public opinion at a particular time and place. The result may be the use of public funds for works which are economically justified, or may be believed to be socially desirable, or even for constructions which represent pure waste and extravagance.

If the individual engineer is opposed to all public works which cannot be shown to be economically sound, he is free, as is every other citizen, to express this as a personal view, but it is an impossible principle for the profession as a whole to bring forward. There are certain basic principles, however, on which the Engineering Profession can agree.

Any work, for example, which does not offer opportunities for adequate financial return to the public treasury through direct service charges, through assessment for benefits, or through the creation of additional values which can be taxed, must be classed from the pure economic standpoint, as a luxury. Presumably, such works can be afforded only when the surplus of public funds permits such construction, or when the public is willing to accept such an additional tax burden as their construction entails. This is not a matter of opinion but a statement of fact.

Now, the engineer is an expert in the investment of funds, public or private, in engineering enterprise. It is his duty not only to design such works to meet the service desired with the utmost skill and economy, but also to advise his client, public or private, as to the probable cost and returns from the investment. The Engineering Profession, therefore, is quite within its scope of duty if it insists that the public shall be advised as to the engineering values of any proposed investment of public funds in a public work of an engineering nature. As far as the writer can see, the engineer's duties as a professional man go no further than this. In fact, if he reads these papers correctly, one of the chief objections which the authors offer to recent Government practice rests on the suppression of adverse engineering reports or the assumption that engineering values can be appraised adequately by a layman. The writer, therefore, feels that a great majority of engineers would support the following statements:

(1) That any proposed investment of public funds in any enterprise of an engineering nature should be investigated by (*a*) competent engineers, not directly concerned with, or interested in, the enterprise, who should be asked to review the project as to (*b*) its feasibility and cost, and (*c*) its economic values, reducing these as far as possible to quantitative terms and stating clearly the limits of precision and certainty of the conclusions; and,

(2) That all such reports be given full publicity.

ELLIOTT J. DENT,[61] M. AM. SOC. C. E. (by letter).—The brief discussion of flood control by Professor Mead is timely, and it is to be regretted that it was not possible to make a more extended statement. There is an urgent need that the general public be informed as to the facts as popular ideas do not include a recognition of the basic causes of flood disaster or the difficulties that must be overcome in order to effect a cure.

The occupancy of the flood-plain does not prove folly on the part of those who have selected sites subject to over-flow for their homes or their business activities. The fact is that the inherent advantages of the bottom-lands are such that they will far outweigh the disadvantage due to an over-flow that may occur once in a generation. A settler moving into a new country may have been wise in deciding that the annual gain due to the selection of a flood-plain site will enable him to set aside a reserve that will more than compensate for the loss due to infrequent flooding. A second settler may build near the first for the same sound reason, a third moves in, and eventually a town or city comes into being. As the town was expanding each individual found it to his advantage to build in the flood-plain rather than on higher ground and each individual takes the measures to guard against flood loss that he considers advisable. In spite of the object lessons afforded by the great floods of recent years, large numbers of residences and business establishments are being currently built in areas that were under water only a year or two ago.

The cost of flood protection for a single building may be far more than is warranted by the infrequent losses due to the incidence of the great floods; the time, however, may arrive when the joint losses of all the occupants of a community may warrant the prosecution of a joint project for their joint protection. In some cases the losses in a number of municipalities in a single water-shed may warrant joint action with a view to the construction of reservoirs for the abatement of the floods as contrasted with the local protection works aimed at their exclusion from selected areas. When a community project can be shown to be economically justified it should be carried forward, but, pending the completion of such a project, a new comer may well find it to his advantage to establish himself in the flood-plain, reap the advantages of the site selected, and stand the loss due to an occasional over-flow. Such choice on his part may be good business, not folly.

Wherever there is a tendency for a municipality to expand in an area subject to occasional over-flow, it may be well for the Public Works Planning Agency to require that each new sub-division make provision for eventual flood protection. Such advance planning may materially reduce the ultimate cost and may thereby make it possible to execute the project at an earlier date than would otherwise be possible.

---

[61] Colonel, U. S. Army (*Retired*), Washington, D. C.

The people of the United States are accustomed to carry fire insurance and the contrast between fire and flood losses may be worth referring to in the educational campaign so badly needed at this time. The ordinary fire loss is confined to a small area; it may be limited to part of a single building; it may include the whole of a single building, or a number of adjacent buildings; a conflagration covering one or more city blocks is most exceptional. A fire loss is ordinarily very heavy for the property actually involved, and of relatively small magnitude when the wealth of the entire community is taken into consideration.

Flood losses, on the other hand, rarely involve the complete destruction of a piece of property, the average loss per premise flooded is probably less than $500. A few weeks after the greatest flood the visible evidence may have almost completely disappeared. From their very nature, however, flood losses cover all developments within a given area which may include a considerable part of a city or of city after city along the valley of the flooded stream. A great flood may last for many days and the multitude of small losses adds up to very large figures, the numbers of persons driven out of their homes create a dramatic situation that appeals to the public. The scare head-lines about loss of life and outbreaks of disease help to raise relief funds but have little factual justification.

Fire losses are intensive and localized, flood losses are less intensive but have some of the characteristics of a widespread conflagration. Flood losses might be made the subject of reasonable insurance rates, but the insuring companies would be facing huge losses at infrequent intervals instead of the relatively well distributed losses due to the incidence of numerous small fires.

An individual planning to invest his own funds in a home or a business must decide for himself whether it is best to locate in the flood-plain, take his profits during the many years of security, and take his losses when the floods come. In the natural course of events those who elect to occupy the lowlands must accept the consequences of their choice. In due time, they may become numerous enough and wealthy enough to make a co-operative flood-control project an economically sound public enterprise. A judicial engineering study will go far toward showing when the proper time for the execution of the project arrives. Advance planning may also result in the reservation of rights of way for use when the project is undertaken and by reducing the cost may advance the date when the work may become economically warranted.

C. FRANK ALLEN,[62] M. AM. SOC. C. E. (by letter).—In Massachusetts, there is a law that no new railroad enterprise shall be authorized without a certificate of exigency from the proper board. There seems to be no board for that purpose in Washington, D. C., and in the projects that have been undertaken, apparently there has been no regard for what might be termed a certificate of exigency. Instead there is a certificate of emergency. Such a certificate does not reach the emergency of the project itself; it is not a reason, but an excuse, for the expenditure of huge sums of money.

---

[62] Prof. Emeritus, Mass. Inst. of Tech., West Roxbury, Mass.

Many of these projects have the element of emergency in the matter of flood control, but, in some cases, flood control has been used as a means for the encouragement of other lines of activity; for instance, power. In the creation of reservoirs for flood control, power is an antagonistic element. For power, a full reservoir is requisite; for flood control, an empty one is requisite; and it is an interesting fact that in the Dayton Flood Control System, a tablet on each of these reservoirs states that it has been designed for flood control and not for storage—in the general sense, not for power.

Engineers should be careful in accepting power accessories as coming within the exigency, or emergency, classes that are established in connection with these huge projects which, apparently, have no economic value.

Most of them have an unfortunate effect in disturbing existing agencies, and there is at present great need for stability. Nearly all of them tend to disturb existing industries, and, to that extent, in many ways, they are unfortunate. For example, why develop irrigation, when it will disturb so many of the established agricultural interests, which have already been restricted by the Government? An important feature of some of the projects is irrigation.

Bradley G. Seitz,[63] **Jun. Am. Soc. C. E.** (by letter).—In his paper Professor Mead maintains that the Federal public works activities of the past several years have been, in general, economically unjustified, and of little benefit to the nation. Professor Mead further contends that radical legislation has been introduced, and that the broadening of governmental activity threatens the income of investors.

The sociol-economic implications of this paper are open to question. The expansion of governmental functions is not a temporary national phenomenon to be deplored; it is the resultant of all the complex forces acting upon modern society, a force to be directed. In England, France, Russia, Sweden, Switzerland, Finland, and Norway, for example, the "Record of the Government in Business" has been written several chapters beyond that in the United States. Most of the legislation referred to as radical has long been accepted by the conservatives of England.

The fact that some public works projects may be uneconomic does not warrant so general a condemnation. It is to be remembered, also, that conventionally sound economic analysis often leads to conclusions which are socially absurd. It cannot be applied, for example, to public education, or garbage collection. During the past few years, it has been economically unsound for industry to employ about 10 000 000 men; and yet the resulting curtailment of production in the face of a need for products, the waste of man-power and machine power, are both technically and socially appalling.

Although increased governmental activity may well result in decreased profits to the investor group, it is obvious that the condition of maximum profit to investors is frequently in sharp conflict with the general welfare. When this conflict occurs, the general welfare should prevail.

Professor Mead cites the inefficiency of the Government in business. From a social, rather than a profit, standpoint the efficiency of business itself is somewhat marred by over-expansion, duplication of effort, the apathy of mechanized workers, the production of unsound or worthless goods, the interruption of production by strikes and lock-outs, wasteful exploitation of natural resources, over-capitalization, excessive sales, advertising and distribution costs, and periodic depressions.

---

[63] Junior Engr., U. S. Engr. Office, Binghamton, N. Y.

These defects are mentioned, not to excuse inefficiency in Government, but rather to suggest that the failure of public enterprise to satisfy the formulas of private enterprise is not, in itself, a valid criticism, since their aims are different.

ALFRED ALLEN STUART,[64] M. AM. SOC. C. E. (by letter).—The papers by Professor Riggs and Colonel Wilgus, especially, have great value, not only because of their able analyses of the subject-matter but also because they expose a great waste of public funds for projects having no appreciable value to the people at large, who must bear the cost. For these several reasons the profession owes a debt of gratitude to each of these authors for bringing to public attention such unwarranted waste of public funds. However, it must be said that the publications of the Society have such a limited circulation among all the people as to preclude the great benefit from being realized.

It is to be regretted that very many of the large works undertaken by the Federal Government are brought to the attention of Congress by incompetent individuals, and are often acted upon favorably by Congress, despite the fact that they may have no merit whatever. It is unfortunate that, as now constituted, the Society has no means of being invited by that body to advise Congress as to the merits, or demerits, of all matters presented to it which, in their very nature, requires a highly trained and experienced civil engineer to comprehend and learn the merits, and demerits, before Congress takes any action on them.

In April, 1906, the writer was asked to go to Portland, Ore., to advise a banking house of New York City as to the merits of an undertaking that would require a large investment of capital. The local newspaper announced his arrival, stating that he represented large financial interests in New York. Immediately following, and continuing as long as he remained in Portland, the writer was importuned by many individuals to interest capital in numerous new developments. Many of these had much merit and could, upon completion, be made very profitable had there been a sufficient number of people to have availed of the benefits to be derived. In view of the fact that as few people were available to utilize the proposed improvements, the writer was compelled to decline even presenting them to the banking interests which he represented.

Congress is constantly having meritorious enterprises presented to it, but as now constituted that body has no means of analyzing them to discover whether they have any merit in fact.

PIERCE P. FURBER,[65] M. AM. SOC. C. E. (by letter).—One aspect of the public works question has not been stressed in the papers of this Symposium.

---

[64] Cons. Engr., Winter Park, Fla.

[65] Wayne, Pa.

Several references were made to the uneconomic character of Government projects, although none of the authors offered to show why this happens, or what fundamental principle is involved. The remarks were largely confined to specific criticism of individual projects as samples of Government inefficiency, and frequently to the relation between good engineering and bad economics displayed in most of them.

Often it has been said that the Government cannot operate any business successfully. Experience seems to confirm that opinion. A primary reason may be: Success in business depends upon management more than any other factor within Man's control. Finance, engineering, construction, operation—able management furnishes the impetus that drives them all. The economic success of a construction project depends primarily not on the soundness of the engineering, but upon whether the total actual cost of the completed work will bear a proper relation to the income which may be derived from its operation. This will follow if the judgment of the promoters is sound. Good management is the basis. Engineers may as well acknowledge this situation; it will do no good to cite excellent engineering design as a justification for any project. Engineering work is a means to an end, not the reason for spending money. Often, engineers themselves furnish the good management so essential to success.

Why cannot the Government match that efficient management which may be discovered within the executive branch of private enterprise? Mainly, because private business is undertaken for profit. Men who risk their capital, and their time, in a venture, naturally possess the necessary selfish interest in it to act as a spur to their wits; energy must be applied constantly to avoid loss of their own money. This applies as well to corporations, whose active stockholders exercise constant vigilance over the acts of directors and managers. Some of the direct urge may be lessened in the case of large companies with enormous numbers of small stockholders This condition serves to emphasize the general principle as it concerns Government business, because it has often been noticed that the efficiency of large corporations which have been "orphaned" by wide dissemination of stock holdings has deteriorated in some degree due to the management no longer having a genuine stake in the company.

There is a difference between occupying an executive position of power which carries small financial responsibility, and holding a large proprietary interest in a business. The proprietor will invariably prove a better manager than his hired assistant, granting that he be not simply a financial "angel."

The chief fault in these Government projects—in any Government venture into the field of business or construction—is that no one responsible for the conduct of affairs is in any way responsible for the financial success. None of the managers, or directors, or administrators, has any stake in the enterprise. They are always spending other people's money—tax money—of which the supply always appears to be inexhaustible. The latter presumption accelerates the tendency to uneconomic operations. If only a certain sum were available, and the director knew it, there might be an incentive to try to make that sum do the work. It is fair to credit every public official with the intention to perform his task satisfactorily and efficiently. Likely enough, very few of them are consciously reckless or extravagant; they want their plans to succeed.

However, they may not possess the quality of judgment required to perceive the defects. Experience of large affairs is nearly imperative for any one by whom large sums of money are to be disposed effectively. Judgments may be hampered, furthermore, by the pressure of interests (political, for instance) which should have no voice in determining policies or formulating plans for a business. Public officers are always plagued by geographical considerations which affect practically every dollar spent upon public works.

Notwithstanding the foregoing comments, the entrance of politics, local or sectional interest, or any other influences that burden the management of Government business, actually does not provide sufficient excuse for the failure of public works to pay their way. Neither is it sufficient to assert that they might be constructed or operated economically if their mangagement could be "taken out of politics." To remove all influence of that kind from the directing head would simply leave him more or less free to do as he pleased, without control from any source except public opinion or his own conscience; lack of financial responsibility would be altered in no sense. There would still be no "pocket-book" urge to caution or prudence, no risk of loss staring him in the face before every important decision.

Direct financial interest makes a difference! There may be altruistic souls who believe that a strong man may put forth the same effort on behalf of others—or the public—that he exerts in his own favor. Examples of such deserving virtue may be found in the field of pure Government or civic service, where success is not measured in money. When the cruel criterion of profit and loss enters, the situation changes remarkably. Detachment from direct financial concern cannot fail to alter any person's view of any proposition from that he would hold if his own welfare were involved. Consider trustees, for example. Honest and capable trustees for others' funds are notoriously conservative; risks are feared, sometimes to the actual detriment of the beneficiary. Weaker men sometimes succumb to the temptation to use their positions for personal gain.

Public officials are human, as much so as trustees. They cannot possibly endow themselves with a disinterested quality, or ability to handle large sums of money in widespread business ventures which will produce results commensurate with the achievements of private persons whose self-interest and ability are all centered on one objective: To make a commercial or economic success of whatever they undertake.

Concerning particular suggestions made in the Symposium, a few comments are offered.

Advance planning is well enough to contemplate, as a theory. The prospect of arranging some program of public improvements to be undertaken in the indefinite future, when the need for work is expected to exceed the amount available, may probably now be considered good social theory. It could scarcely be considered good economic theory at any time. The only natural, or rational, economic justification for any building project is either that the construction is needed, or that the improved property will produce income. Governmental projects may be justified by the former; private, or business projects, by the latter consideration.

"Build if, and when (and only if and when) additional space is needed" is a good rule for any business. Successful and growing business applies this rule quite generally, regardless of outside conditions, much the same as large investors, such as insurance companies, handle investment funds; they buy securities when they have idle capital to invest. Waiting for a more favorable market may mean missing the market entirely, or incurring a loss of income. Postponing a building operation may mean loss of time more valuable than the possible increased cost at current prices. Advancing a building project may mean a total failure if the plant is found unnecessary when completed.

Therefore, from an economic viewpoint, success depends upon the decision of some one that the work is needed and should be undertaken at a particular time. Able management is thus the guide to proper timing, also.

Improvements included now in a program for later development during some future depression might be found inadequate, or even undesirable when the time arrives for their execution. No one can foresee the material necessities of even a few years hence. There are many examples of structures planned (at considerable expense) for future extensions, which have not been made and may never be.

The best plans are not always those upon which much time has been spent. A more important factor than time is involved in good design, or planning, namely, brains. That keen sense of discernment, which can be neither explained nor defined, which some possess and others lack, which leads some men directly to practical solutions of difficult problems, outweighs every other qualification of a prospective manager or designer. Obviously, reasonable time is necessary to any work. More time than that spent on reviewing possible methods, especially in conferences, may be the cause of inferior plans. Advance planning, especially for long deferred projects, might easily produce just that condition.

The criticism of public works presented in this Symposium indicates not so much that dissatisfaction is expressed because the projects were hastily planned, as that most of them should never have been planned at all. All the large projects discussed are extremely questionable ventures. Perhaps none of them would have been undertaken had a serious and honest balance been drawn between economy and expediency. The least competent engineer may readily understand, without deep research, that the Florida Canal, Passamaquoddy, Grand Coulee, or TVA, will never be worth their cost if measured by the same standard ordinarily established for lesser operations. Why should not they be so judged?

Whoever attempts to justify this huge construction program as economically feasible is invited to answer or consider a hypothetical question: Could these projects ever be financed if the Government had to attract private capital instead of compelling it through taxation?

True enough, Government bonds have a market; but not on account of the security afforded by public property. They are in no sense a lien upon it. They may be regarded as a satisfactory investment for one reason only: The Government has power to tax the people to pay its debts. Failing this (if, for instance, an extravagant Government should borrow, and spend, more than it could possibly collect in taxes), only one course would be open—repudiation; because, whereas bankrupt corporations liquidate or reorganize, Governments repudiate, directly or indirectly. A Government may issue so-called money (paper notes) to retire its so-called bonds, or it may simply neglect to pay them at all, or it may refuse to pay them. Then, the bondholder has no recourse. No legal security exists for the holder of Government bonds. A bankrupt Government may not be called into Court for liquidation. The creditor's rights are determined by the debtor's pleasure, or good faith. Witness the World War loans.

This situation forces the conclusion that, ultimately, the Government itself is as irresponsible, financially, as any of its agents or officers, when considering the economic aspects of public works. It is liable only to the extent it chooses to be; it may cancel or abridge its agreements with impunity, wherever the executive has discretionary power; otherwise, by Act of Congress. As no one concerned with borrowing or spending these fabulous sums has any direct responsibility for their wise administration or expenditure, neither has the Government, as an entity, any responsibility. Executive discretion may be controlled, or legislative aims directed (after a fashion) only at the ballot box, and not there, even, in case of many appointive officers. Past official action is subject to scarcely any redress, although it may have caused serious damage.

Government extravagance differs from private waste in one important respect: The former wastes public money, the latter wastes its own. The former, therefore, is far more reprehensible, contrary to the cynical notion many people entertain that the Treasury is a huge grab-bag, a bottomless mine to be worked by clever people for their own benefit.

Any unnecessary public works are a drain on the national wealth and welfare. Business projects conceived in false economy, and executed extravagantly, will lead a Government as surely into bankruptcy as similar mismanagement will wreck a private business. The principle is the same, the distinction being one of degree. The evil day may be longer deferred by a Government's using powers denied to private persons.

Whether the Government programs will constitute a national policy, or portend increasing public ownership and operation of business probably depends on how long the people may take to realize the extent of the uneconomic works already under way, and that they are to pay the cost themselves. When they have reached the inevitable conclusion that the management of public business is irresponsible, under all circumstances, they should understand the futility of entrusting economic problems to Government. The necessary functions of pure government (national defense, protection of public safety, etc.) fall into an entirely different category.

The Engineering Profession may serve the country by hastening to develop the national understanding of this momentous question. Its members should view the subject patriotically, and express their deliberate opinions with a single purpose for the best interest of the entire country. It is a subject fit to challenge one's devotion to the truth; a test for one's claim to high ideals. Let engineers hold to the course of reason and common sense, no matter what ignorance or sophistry may argue to the contrary.

Colonel Wilgus cites the vision of certain builders, cautioning that vision is an attribute of unknown value. It is one element of the sense, or judgment, emphasized herein. Vision, however, varies with the point of view. Another hypothetical question is submitted: Would any sensible, level-headed manager, or board of directors—any that ever lived—use their own funds to build these public works if they, themselves, had to assume the risk of possible failure with the attendant losses? (Assume, of course, that they would be entitled to whatever profits might accrue.)

Is it not a question of whose vision to trust? Unless vision is accompanied by substantial financial capacity it seldom inspires confidence. The Canadian Pacific Railroad and the Grand Central Terminal illustrate the point admirably. In these projects, vision, backed by capital, carried responsibility. The vision that promulgated the Florida Canal was devoid of it.

Apparently, some projects have been ordered built in spite of adverse reports by competent engineers. Such proceedings confirm the belief that lack of financial responsibility leads to recklessness, inefficiency, and waste. A responsible executive would hesitate before committing himself or his company to a policy involving large expenditures after receiving not only one, but perhaps several, very discouraging expert reports upon the economic feasibility of a proposition.

The inception of these public works brings to mind the figure of Peer Gynt, in Act IV, Scene V, of Henrik Ibsen's play. Stranded in Morocco, Peter Gynt has wandered inland to a place overlooking the Sahara Desert. After a soliloquy as to the "enormous boundless waste" stretching out before him, he is inspired by an idea:

> "A dam! Then I might ——! The hills are low.
> A dam! Then a cutting—a canal—
> And through the gap the rushing waters
> Would fill the desert with a life-flood."

Then, his thoughts rushing out with a frenzy of idealistic zeal, he visualizes town after town growing up in the Sahara Desert—new industries, new trade, new discoveries; and, finally, with settled conviction, he springs up:

> "I only need
> Some capital, and the thing is done—
> A golden key, and the ocean's gate
> Is open! * * *"

R. F. BESSEY,[66] M. AM. SOC. C. E. (by letter).—This Symposium is disappointing because, essentially, the papers (except that by Mr. Fay) represent only one viewpoint of the subject. With Mr. Fay's suggestions for orderly investigation and planning of public works the profession should be in hearty accord. He also suggests, in developing his thesis, some of the fundamental national economic considerations relating to public works, namely, unemployment, the business cycle, national income, the construction industry, public finance, etc.

---

[66] Consultant, National Resources Committee, Pacific Northwest Regional Planning Comm., Portland, Ore.

As to the remainder of the Symposium, the dominant note is one of criticism and the general inference is that current programs for large public works are uneconomic and unsound. With the constructive suggestions, that public works economics should be studied and discussed by the Engineering Profession, there should be general agreement.

It is not the purpose of the writer to undertake a detailed defense of the projects questioned. Rather, it is his intention to urge a deeper and more general consideration of the economics of public works by all engineers, and briefly to indicate some of the broader economic considerations relating to the public works of the Pacific Northwest.

It is hoped that the Symposium will bring more professional thought to the fundamental economic and social factors—in addition to the purely physical and financial factors—in the design of public works. If engineers are to be of optimum value to society, and are to take the valuable place in public affairs that their basic training warrants, they should acquire a certain knowledge and appreciation of economic, social, and governmental factors. It should be understood, however, that public works is not the field of the engineer exclusively; the engineer must learn to work co-operatively with the economists, the social and political scientists, and the legislators and administrators, who are also vitally concerned.

It is obvious that the economic factors relating to public works are somewhat different from those of private engineering works; also that the factors for the large public projects may be somewhat different from those of the smaller ones. Essentially, the test of the economic feasibility of the private work is profit or loss. Essentially, the test of public work is the extent of public benefit. This is public profit or loss, but all the items are not necessarily measurable in dollars and cents. The smaller public works are quite often designed for a single purpose and the tests of economic merit may be relatively simple: Does the project provide the particular improvement or service needed? Does it fit into a comprehensive plan? Is it physically feasible? Is it legally and administratively feasible? Can it be financed? Will the value of service cover the cost, including capital, interest and amortization, maintenance and operating expenses?

The larger projects involve these tests also; but, in addition, other factors (many of them of a more imponderable nature) must also be taken into consideration. For example, the most important test of the need of a water supply system may be whether a great metropolitan area can continue to grow, or even survive, without such a system. With respect to a slum clearance and housing development, the tests are not solely whether rentals will pay the fixed and operating charges, but whether a community can afford to continue to pay the estimably greater upkeep cost of the blighted area or the inestimably great social costs of the slums.

Public works should be considered as one of the available means of economic adjustment—not only with respect to unemployment of labor, industry, and capital, and the swings of the business cycle, but in correction of, or compensation for, community or regional deficiencies, or unfavorable economic conditions or balances.

Without attempting to elaborate, criteria for larger public works would involve, in addition to comparison of cost and income, or cost and direct benefits, the weighing of various socio-economic factors, including their effect on: (*a*) The stability or movement of population; (*b*) the flow of wealth; (*c*) the economic activities of the community; (*d*) patterns and standards of life; (*e*) public welfare—health, education, safety, recreation, etc.; (*f*) other programs and projects; and (*g*) the conservation and beneficial use of resources, including those of land, soil, water, minerals, etc. Some of these effects might be illustrated by brief discussion of one or two classes of public programs and public projects.

Irrigation development permits a more intensive and stable use of land. In some areas of the United States, very large and important segments of rural and urban civilization would wane and many communities would disappear without it. Irrigation development also involves such economic considerations as movements of population, changes in the pattern of agricultural production, new agricultural industries, and new rural markets. Therefore, the tests of the economic merit for an irrigation project are not merely whether the water users pay their fees and amortize the cost on time; the more indirect effects, the community wealth created, the taxes paid, etc., must also be considered. Reference to a study of the Washington State Planning Council on this subject[67] should broaden the view of some of those who may look at irrigation economics only in terms of project cost and direct repayment. The report of the Council points out that the Yakima Valley, developed through irrigation, produces as much as $50 000 000 annually in farm products, livestock, and value added to raw materials through manufacture; also that, of the new wealth, produced annually, more than one-half is expended for the products of Eastern industries.

Projects for water supply, water conservation, etc., have high importance in any region, but in the Western United States civilization cannot advance, or even be maintained at present levels, without them. Conditions in the high plains[68] point to the great importance of such projects, and also emphasize the principle that in the planning, design, and financing of public works, the fundamental social and economic needs of the community should be determined and such resources as are available for public works should be devoted to meeting these needs in proportion to their importance and urgency, rather than on the basis of custom or precedent.

The economics of hydro-electric power development involve much more than a comparison of costs of fuel-generated and water power; such factors as the conservation of a national fuel and chemical supply (the dwindling oil reserves, for example), and the auxiliary effects of river control (in navigation or irrigation, for example), must also be weighed.

Pointing this discussion more specifically toward the economics of large Pacific Northwest projects concerning which questions are raised in the Symposium: The large projects in the Pacific Northwest are essential to this relatively young region, which cannot meet some of the present needs and cannot advance materially without measures of this kind.

[67] "Reclamation—A Sound National Policy, as Demonstrated by the Yakima Valley and Other Irrigated Areas in Washington," Washington State Planning Council, 1936.

[68] "The Future of the Great Plains," Rept. of the Great Plains Committee, December, 1936.

Land is a fundamental factor in the Pacific Northwest, as elsewhere. The Pacific Northwest[69] includes 300 000 to 350 000 sq miles, depending on how it is defined. The four Pacific Northwest States of Washington, Oregon, Idaho, and Montana, contain nearly 400 000 sq miles, about 13% of the area of the United States, and less than 3% of the national population. The crop land in these States is limited in extent; it is only about 26 000 000 acres out of a total of 254 000 000, and its productive capacity is generally limited without water.

Lands at present under irrigation total about 5 000 000 acres. There are feasibly irrigable as many as 6 000 000 acres more. Of this area, about 1 200 000 acres lie in the Columbia River Basin, under the Grand Coulee Project. The net additional total of crop land feasibly reclaimable by other means—drainage, diking, stump clearing—is not definitely known, but perhaps would total an additional 2 000 000 to 4 000 000 acres.

Reclamation in the Pacific Northwest also bears an important relationship to national land needs and programs.[70] For example, it should be considered in relation to the indicated need of retirement, nationally, of about 25 000 000 acres from cropping as a soil conservation measure and to 30 000 000 acres, or more, which will be required during the next generation to meet the needs of new population. In addition, or perhaps tending to offset technological advances in land use, there undoubtedly will be a large land requirement during the next generation to meet the growing need of production of industrial raw materials. Mr. J. W. Haw discussed some of the national economic factors in land reclamation before the Annual Convention of the Society in 1936.[71]
